Journal of the Society of Chemical Industry.

INDEX OF VOL. VI.—1887.

INDEX OF AUTHORS' NAMES.

INDEX OF SUBJECTS.

LIST OF MEMBERS.

A

Abbott, John, Braemar House, Lancaster Gate, Hyde Park, W.
Abel, Sir F. A., Royal Arsenal, Woolwich, London, S.E.
Abney, W. de W., Capt., Willeslie House, Wetherby Road, South Kensington, S.W.
Abraham, A. C., 87, Bold street, Liverpool
Acland, Sir H. W., Radclyffe Library, Oxford
Adam, A. Learmouth, 40, Sir Michael Street, Greenock, N.B.
Adam, J. B., 172, Leith Walk, Edinburgh
Adams, M. A., Ashford Road, Maidstone, Kent
Adams, J. W., 74, Oxford Street, Regent Road, Salford, Manchester
Addenbrooke, Edwin, 18, Cawley Road, South Hackney, E.
Addie, J., Langloan Ironworks, Coatbridge, N.B.
Addyman, F. T., Laboratory of Roy. Agric. Soc., 12, Hanover Square, London, W.
Adkins, H., Chemical Works, Smethwick
Affleck, J., Mill House, Woolton, near Liverpool
Aikman, Charles M., 183, St. Vincent Street, Glasgow
Aitken, A. P., 8, Clyde Street, Edinburgh
Aitken, J. B., Gerard's Fold Chemical Works, Widnes
Akitt, Thomas, Belsund Factory, Tirhoot, India
Albright, G, S., The Elms, Park Road, Edgbaston
Albright, W. A., Marièmont, Birmingham
Allbright, W. B., Dorchester, Mass., U.S.A.
Alexander, J.O., 4, Belhaven Terrace, Kelvinside, Glasgow
Alexander, W, T., 20, Booth Street, Mosley Street, Manchester; and Crumnock Bank, Victoria Crescent, Eccles
Allan, Jno., 2, Blythwood Villas, Crouch Hill, N.
Alldred, C. H., 35, Crisp Terrace, Upper Park Road, Plumstead Common, Kent
Allen, A. H., Sydenham Cottage, Park Lane, Sheffield
Allen, J., 164, Upper North Street, Poplar, London, E.
Allen, J. Fenwick, Newham, Whalley Range, Manchester
Allen, Walter S., 13 Beacon St., Boston, Mass., U.S.A.
Allen, Wm., Edenholme, Bournemouth, Hants
Allen, W. H., c/o F. Stearns & Co., Detroit, Mich., U.S.A.
Allender, G. M., Stammerham, Horsham, Sussex
Allhusen, A., Gateshead-on-Tyne
Allhusen, Wilton, 102, Quay Side, Newcastle-on-Tyne
Allibon, G. H., Seaview, Litherland Park, near Liverpool
Alsberg, M. (Sondheim, Alsberg & Co.), P.O. Box 2437, New York, U.S.A.
Anderson, C. Torre, Messrs. Bass & Co., Burton-on-Trent
Anderson, Geo. B., Victoria Square, Felling-on-Tyne
Anderson, John, Glengarnock Ironworks, Ayrshire, N.B.
Anderson, J. M. T., Explosives Co., Ld., Stowmarket, Suffolk
Anderton, G. H., Howendyke, Howden, Yorks.
Angell, J., The Grammar School, Manchester
Angus, James, Lugar, Ayrshire, N.B.
Angus, John, Ingram House, 165, Fenchurch St., London, E.C.
Angus, W. Mathwin, St. John's Leather Works, Newcastle-on-Tyne
Annandale, J. H., Polton, Midlothian, N.B.
Annison, R. H., 16, Water Lane, Tower Street, London, E.C.
Ansdell, G., 45, Courtfield Rd., South Kensington, S.W.
Ansdell, T. C., Kearsley Cottage, Farnworth, Bolton
Archbold, George, Laboratory, Phœnix, Oswego Co., N.Y., U.S.A.
Archbutt, L., Argyle Terrace, Rose Hill, Derby
Armstrong, Dr. H. E., Central Institution, Exhibition Road, London. S.W.
Armstrong, Sir William G., Newcastle-upon-Tyne
Ash, T. E., 4, Saltram Place, Citadel Road, Plymouth
Ashwell, H., Woodthorpe Grange, Sherwood, Nottingham
Ashwell, J. H., Woodthorpe Grange, Sherwood, Nottingham
Ashwell, J. R., Midanbury Lodge, Bentinck Road, The Forest, Nottingham
Ashworth, L., The Barlows, Radcliffe, near Manchester
Aston, Theo., 11, New Square, Lincoln's Inn, London, W.C.
Atcherley, R. J., 37. Ashchurch Grove, Starch Green, W.
Atkins, S. R., Market Place, Salisbury
Atkinson, A. J., 44, Loudoun Square, Cardiff
Atkinson, Geo., Aldersgate Chemical Works, Southall, Middlesex; and 66, Aldersgate Street, London, E.C.
Atkinson, R. W., 44, Loudoun Square, Cardiff
Attfield, J., Ashlands, Watford, Hertfordshire
Aubrey, W. H., Caledonia Estate, Province Wellesley, Penang
Auer, H., Lathom House, Halebank, near Widnes
Auerbach, C. G., Farbenfabriken vorm. F. Bayer & Co., Elberfeld, Germany
Austin, E., 126, Bermondsey Street, London, S.E.
Aykroyd, W. H., Oakwood Villas, Toller Lane, Manningham, Bradford, Yorks.

B

Bailey, Edwin M., Royal Bank of Scotland, Ardrossan, Ayrshire; and 38, Berkeley Street, Glasgow
Bailey, Wm., The Terrace, Oaken, near Wolverhampton
Bailey, G. H., Owens College, Manchester
Bainbridge, Herbert A., Union Club, Trafalgar Square, London, S.W.
Baker, E., Stoneleigh, Eastern Avenue, Reading, Berks.
Baker, Harry, 262, Plymouth Grove, Manchester
Baker, W. G., Garden Wharf, Church Road, Battersea, London, S.W.
Baker, Theodore, Clifden, Overcliff, Gravesend
Bald, J. H., Braddock, Pa., U.S.A.
Ball, T. B., 12, Edmund Street, Rochdale
Ballard, E. G., Queen's Park, St. Helens
Ballard, J. F., Somerby Villa, Norfolk Park, Maidenhead
Bamber, H. K., 5, Westminster Chambers, Victoria Street, London, S.W.
Banister, H. C., 31, Dale Street, Liverpool

Banks, Arthur J., 229, Wavertree Road, Liverpool ; and c/o Jas. Morrell & Co. Limited, Morpeth Dock, Birkenhead
Banner, Samuel, 4, Ivanhoe Road, Liverpool
Bannister, R., The Laboratory, Somerset House, London, W.C.
Bannister, W., 108, Patrick Street, Cork, Ireland
Barclay, H., Rose Hill, Harrington, Cumberland
Barclay, Thos., 17, Ball Street, Birmingham
Bardsley, Robt., c/o Jewsbury & Brown, 44, Downing St., Manchester
Barlow, E., 2, Old Palace Yard, Westminster, S.W.
Barnes, H. J., Phœnix Chemical Works, Hackney Wick, E.
Barnes, J., 37, Avenue Parade, Accrington, Lancashire
Barnes, Jonathan, Buckton Vale, near Stalybridge
Barnes, R. L., Phœnix Chemical Works, Hackney Wick, E.
Barr, J., Dinting Vale, Glossop
Barr, R., 44, Granby Terrace, Hill Head, Glasgow
Barret, E. L., 53, Springfield Road, St. John's Wood, London, N.W.
Barrow, J., Helme House, Sandwich Road, Ellesmere Park, Eccles, Manchester
Barrow, Jos., Oldham Road, Failsworth, Manchester
Bartholomew, G., Halstow House, Windsor Road, Forest Gate, London, E.
Bassett, H., 26, Belitha Villas, Barnsbury, N.
Bateson, Percy, Emsworth, Wavertree, Liverpool
Battershall, Jesse P., 402, Washington Street, New York, U.S.A.
Batty, R. B., Drayton Villa, Erdington, near Birmingham
Baxter, W. H., The Lawn, Brixton Hill, London, S.W.
Bayley, F. S., 88, King Street, Manchester
Bayley, Thos., 7, West End Chambers, Broad Street Corner, Birmingham
Baynes, J., jun., Royal Chambers, Scale Lane, Hull
Beadle, Clayton, Beadon Well, Belvidere, Kent
Beanes, E., Moatlands, Paddock Wood, Brenchley, Kent
Beardmore, Wm., Parkhead Forge, Glasgow
Beaven, E. S., 5, Boreham Terrace, Warminster, Wilts.
Bechler, M., The Manbré Saccharine Co., Limited, Fulham Road, Hammersmith, London, W.
Beckett, G. H., Hartford, Khedive Road, Forest Gate, E.
Beckett, J. H., Wilmslow Park, Cheshire
Beckingham, J. H., Messrs. Scott Brothers, Royal Insurance Buildings, Newcastle-on-Tyne
Bedford, J., Woodhouse Cliff, Leeds
Bedingfield, C. H., 4, Tichborne Street, High Fields, Leicester
Bedson, P. P., Durham College of Science, Newcastle-on-Tyne
Beilby, G., St. Kitts, Slateford, N.B.
Belcher, J. C., 19, Charles St., Marine Parade, Brighton
Bell, C. Lowthian, Middlesbrough-on-Tees
Bell, G., Runcorn Soap and Alkali Co., Runcorn
Bell, H. S., 2, St. Anne's Park Villas, Wandsworth, S.W.
Bell, Jno., 118, Southwark Street, London, S.E.
Bell, J. Carter, Bankfield, The Cliff, Higher Broughton, Manchester
Bell, Sir I. Lowthian, Bart., Rounton Grange, Northallerton
Bell, J. Ferguson, Stafford
Bell, J. Ralston, Appleby Iron Co., Frodingham, Doncaster
Bell, Jno., Millburn, Renfrew, N.B.
Bell, O., 13, Northumberland Terrace, Tynemouth
Bell, T. Hugh, Middlesbrough-on-Tees
Bellingham, Wm., Dalston Distillery, London, E.
Bendix, D., The British Alizarin Co., Limited, Silvertown, Victoria Docks, London, E.
Benger, F. B., 7, Exchange Street, Manchester
Benjamin, M., 43, East 67th Street, New York, U.S.A.
Bennett, James M., 12, Hamilton Drive, Hillhead, Glasgow
Bennett, Thos., Birch Vale, near Stockport
Bennie, J. W., Guaranteed Manure Works, Cubitt Town, E.
Bentley, J. W., Stakehill Works, Castleton, Manchester
Benton, W. E., Littleworth House, Hednesford, Staffordshire
Berdoe, Walter, 51, South John Street, Liverpool
Beringer, J. J., 10, South Terrace, Camborne, Cornwall
Beringer, C., 67, Farrant Avenue, Wood Green, London, N.
Bernays, J., 96, Newgate Street, London, E.C.
Berry, E. E., 76, George Street, Gower Street, London, N.W.
Best, T. T., 4, Markt Platz, Erlangen, Bavaria
Bevan, A., Bryn Chemical Works, Llanelly, S. Wales
Bevan, E. J., 4, New Court, Lincoln's Inn, London, W.C.
Bevan, I., Llanelly Chemical Works, Llanelly, S. Wales
Bevan, J. Williams, Southview House, Shirehampton, near Bristol
Bevan, Thos., 122, Cheshire View, Broad Street, Pendleton, Lancashire
Beveridge, J., 19, Rectory Road, Cardiff
Bewick, T. Burrell, Hebburn-on-Tyne
Bibby, E. V., Garston Copper Works, Garston, near Liverpool
Bickerdike, W. E., Clayton Grange, Wilpshire, near Blackburn
Bickerton, C. W., The Hollies, Bosden, near Stockport
Bickett, J. H., Medical College, London Hospital, E.
Biggart, J. Wm., 29, Cathcart Street, Greenock, N.B.
Biggs, B., 3, Lawrence Pountney Hill, London, E.C.
Bihn, G. F., Pennsylvania Salt Manufacturing Co., Philadelphia, U.S.A.
Billing, H. S., Messrs. Burnard, Lack & Alger, Plymouth Chemical Works, Plymouth
Bindschedler, R., Société pour l'Industrie Chimique, Basle, Switzerland
Bingley, J., Chemical Laboratory, Northampton
Binks, J. B., 4, Criffel Street, Silloth, Cumberland
Binney, H. A., Sutton, St. Helens
Bird, R., Ellerslie, Roath, Cardiff
Birley, R. K., Messrs. Chas. Macintosh & Co., Cambridge Street, Manchester
Birch, R. W. Peregrine, 2, Westminster Chambers, Victoria Street, London, S.W.
Bischof, Gustav, 4, Hart St., Bloomsbury, London, W.C.
Bishop, Frank, 6, Holly Terrace, West Hill, Highgate, N.
Bishop, Fred, 12, Charles Street, Edinburgh
Bishop, Jos. J. F., 39, Market Street, Manchester
Bishop, A. Conway, Three Mills Lane, Bromley-by-Bow, London, E.
Bishop, G. A., Royal Bank House, Coatbridge, N.B.
Black, Wm., St. Bede Chemical Co., Newcastle-upon-Tyne
Black, Wm., Stanrigg, Airdrie, N.B.
Blackwell, G. G., 26, Chapel Street, Liverpool
Blades, C. M., Stanley Mount, Northwich, Cheshire
Blagden, W. G., 1, Fenchurch Avenue, London, E.C.
Blair, J., Irvine Bank Chemical Works, Kilmarnock, Ayrshire
Blake, C. A., 47, Piccadilly, London, W.
Blake, F. C., Mansfield Valley Allegheny Co., Pa., U.S.A.
Blake, Jas., Thames Sugar Refinery, Silvertown, London, E.
Blenkinsop, W., Garden Wharf, Battersea, London, S.W.
Bles, A. J. S., 32, Chorlton Street, Manchester
Blinkhorn, W. J., 31, Grove Park, Liverpool
Blount, Bertram, 23, Queen Anne's Gate, Westminster, S.W.
Blundstone, E. R., 10, Wellington Mansions, North Bank, Regent's Park, N.W.
Blythe, F. C., Newholme, Victoria Park, Manchester
Blythe, H. F., Holland Bank Chemical Works, Church, near Accrington
Blyton, J., 12, Cromford Court, Market Street, Manchester
Boa, Peter, 119, George Street, Edinburgh
Boake, A., Highgate, London, N.
Board, J. T., Distillery, Cheese Lane, Bristol
Bogle, Wm., Wappinger's Falls, Duchess Co., N.Y., U.S.A.
Bolas, Thos., 8, Grove Terrace, Chiswick, W.
Bolton, C. A., 40, Carlton Street, Nottingham
Bolton, G. H., Widnes Alkali Co., Limited, Widnes
Booth, Geo., Irk Vale Dyeworks, Middleton, near Manchester

Borland, John, Etruria, Kilmarnock, N.B.
Borland, W. D., 35, Petherton Road, Highbury New Park, N.
Boston, H. G., Nunthorpe Crescent, Bishopthorpe Road, York
Bothamley, C. H., Yorkshire College, Leeds
Böttinger, H. T., Elberfeld, Germany
Bottle, Alex., 4, Godwyne Road, Dover
Boulton, H. E., 64, Cannon Street, London, E.C.
Boulton, S. B., 64, Cannon Street, London, E.C.
Boulton, T. S., Mountford House, Barnsbury Square, London, N.
Bountiff, G. R., Cloncurry Copper and Smelting Company, Cloncurry, Queensland
Bourcart, R., 18, Chaussée de Dornach, Mulhouse, Alsace
Bow, R. H., 7, South Gray Street, Edinburgh
Bowen, S. B., Brickfield Chemical Works, Llanelly, South Wales
Bower, G., St. Neots, Huntingdonshire
Bower, H., P.O. Box 946, Philadelphia, Pa., U.S.A.
Bowler, G. S., Crystal Palace District Gas Co., Limited, Lower Sydenham, S.W.
Bowley, Jos. John, Wellington Works, Battersea Bridge, London, S.W.
Bowly, J. E., Elm House, Trinity Road, Birchfield, Birmingham
Bowman, F. H., West Mount, Halifax
Bowman R., Eglington Chemical Works, Irvine, N.B.
Bowrey, J. J., Kingston, Jamaica; West Indies
Boyd, Pythagoras, Box 77, North Adams, Mass., U.S.A.
Boyd, W., Tharsis Works, East Moors, Cardiff
Boyd W., c/o Messrs. Tennant & Co., St. Rollox, Glasgow
Bracewell, Wm., Brinscall, near Chorley
Bradburn, J. A., 5, Chester Road, Northwich
Bradbury, A., Mason's Buildings, Exchange Street East, Liverpool
Bradbury, W. A., Steetley Chemical Works, Worksop
Braden, Herman
Bradley, N., 49 and 51, Chapman Street, Hulme, Manchester
Bramham, W., 82, Bow Road, London, E.
Bramley, Wm., 18, Clarence Street, Middlesbro'-on-Tees
Bramwell, E., Charlwood House, Huyton, near Liverpool
Bramwell, Sir F., 5, Great George Street, Westminster, London, S.W.
Bramwell, G. H., Cowley Hill, St. Helens, Lancashire
Bramwell, Samuel, 4, St. Ann's Square, Manchester
Branson, F. W., 14, Commercial Street, Leeds
Bray, Geo., Blackman Lane, Leeds
Brayne, Francis W., Bow Pottery, Three Mills Lane, Bromley-by-Bow, E.
Breckon, J. R., 32, Fawcett Street, Sunderland
Breen, George, Irvine Chemical Co., Limited, 204, Vincent Street, Glasgow
Brenemann, A. A., 97, Water Street, New York, U.S.A.
Brewis, E. T., 111, Great Brunswick Street, Dublin
Briant, L., 24, Holborn Viaduct, London, E.C.
Briggs, T. Lynton, c/o Read, Holliday & Sons, Huddersfield
Briggs, W., Springfield Terrace, Arbroath, N.B.
Brinjes, J. H., Whitechapel Engine Works, Fieldgate Street, London, E.
Bristow, G. W., Worcester House, 35, Eastcheap, London, E.C.
Broad, Jas., 66, High Street, Lewes, Sussex
Brock, J., British Alkali Works, Widnes
Brooke, Edwd., Oakley House, Edgerton, Huddersfield
Brookes, E. A., 15, Withington Road, Whalley Range, Manchester
Brotherton, E. A., Fern Cliffe, Ilkley, Yorkshire
Brown, A. Crum, 8, Belgrave Crescent, Edinburgh
Brown, Arthur E., Morden Cliff, Lewisham, S.E.
Brown, D., 93, Abbey Hill, Edinburgh
Brown, D., Donaghmore, Tyrone, Ireland
Brown, H., Royal Oak Brewery, Stockport
Brown, J. Campbell, 27, Abercrombie Square, Liverpool
Brown, J. Kinniburgh, 5, Saxe Coburg Place, Edinburgh
Brown, J. T., 46, Kilmaine Road, Fulham, London, S.W.
Brown, Oliphant A., Lennoxmill, Lennoxtown, N.B.
Brown, T., The Chemical Works, King's Lynn
Brown, Horace T., 47, High Street, Burton-on-Trent
Brown, Walter, c/o Jas. H. Dennis & Co., Widnes
Brown, F. W., 17, Walterton Road, St. Peter's Park, London, W.
Brown, S. B., Strines, near Stockport
Brown, W. A., Overton Paper Mills, Greenock, N.B.
Browning, W., Broad Oak, Accrington
Bruce, Edw. M., Union Pacific R. R., Omaha, Nebraska, U.S.A.
Brundrett, A., Rhymney Ironworks, Monmouthshire
Brunner, H., Cliff House, Appleton, Widnes
Brunner, J. F. L., Trinity Hall, Cambridge
Brunner, J. T., Winnington, Northwich
Brunner, J. P., 28, Exchange Street East, Liverpool
Bryan, E., Gas Works, Beverley, East Yorkshire
Bryce. A. S., Glenpark Oil Works, East Nelson Street, Glasgow
Bryce, A. S., jun., 8, Broompark Terrace, Dennistown, Glasgow
Buch, Carl Von, 17, Cavendish Place, London, W.
Buchan, A., 13, Willowbank Crescent, Glasgow
Buchanan, J. Y., 10, Moray Place, Edinburgh
Buckeridge, Herbert L., 53, Palace Road, Crouch End, N.
Buckley, W., Brookside Printworks, West Leigh, Lancashire
Budden, E. R., Camelot, Netherhall Terrace, South Hampstead, N.W.
Bullock, J. L., 3, Hanover Street, Hanover Square, London, W.
Bumby, H., Solway Ironworks, Maryport, Cumberland
Bunker, H. E., 24, Great Cheetham Street West, Lower Broughton, Manchester
Burdekin, G., jun., Sutton Lodge Chemical Co., St. Helens
Burghardt, C. A., Bridgwater Club Chambers, 110, King Street, Manchester; and Owens College, Manchester
Burgmann, C. F., 41, Warwick Gardens, Kensington, W.
Burnard, R., Plymouth Chemical Works, Plymouth
Burnett, E. E., 118, Huddleston Road, Tufnell Park, London, N.
Burrell, B. A., Bank Chambers, 70, South Mall, Cork
Burroughs, S. M., Bell Lane, Wandsworth, S.W.
Burton. F., 2, Green Street, Bethnal Green, E.
Bury, J. H., Church Chemical Works, near Accrington
Bush, R. A., 20, Artillery Lane, London, E.C.
Bush, W. E., 20, Artillery Lane, London, E.C.
Bush, W. J., 20, Artillery Lane, London, E.C.
Bushill, C. D. T., Broom Hill, Great Barr, Birmingham
Butt, E. N., 25, Sussex Gardens, Hyde Park, London, W.
Butler, Samuel, Compton, Wolverhampton
Butler, W. W., Crown Brewery, Broad Street, Birmingham
Butterfield, J. C., Westbury Cottage, Barking
Button, H., Faraday Chemical Works, Rainham, Essex
Byard, A. G., 70, Fisher Street, Canning Town, E.
Bythway, M., 43, Lloyd Street, Albert Square, Manchester

C

Cabot, Godfrey L., 82, Water Street, Boston, Mass., U.S.A.
Calderwood, J., 1, Alverton Villas, Wandsworth Common, London, S.W.; and Price's Patent Candle Co., Battersea
Caley, A. J., Chapel Field, Norwich
Callard, S., Pontamman Chemical Works, Ammanford, Carmarthen
Calvert, J. H., Oakenshaw Printworks, Clayton-le-Moors, Accrington
Cameron, Ian, Nickel Co., Kirkintilloch, N.B.
Cameron, R., Priory Lodge, Blantyre, Lanarkshire
Cammack, J., 8, Salisbury Street, St. Helens
Campbell, A., 19, Harold Road, Upton Park, Essex
Campbell, Andrew, Linlithgow Oil Co., Linlithgow, N.B.

Campbell, John, 25, New Chambers Street, New York, U.S.A.
Cannon, M., Beaufoy's Chemical Works, Lavender Hill, London, S.W.
Carey, E., Widnes, Lancashire
Carey, W. H., Forest Works, Bulwell, near Nottingham
Carlile, T., 27, St. Vincent Place, Glasgow
Carlyle, W. A., The Elms, Yardley, Worcestershire
Carmody, Patrick, Laboratory, Somerset House, London, W.C.
Carnelly, Thos., University College, Dundee
Caro, H., Mannheim, Germany
Carpenter, H. S., 32, Holborn Viaduct, London, E.C.
Carpenter, R. F., Bent Terrace, Prestwich, near Manchester
Carpenter, W. L., 36, Craven Park, Harlesden, London, N.W.
Carran, T. W., Girton House, Shiel Road, Liverpool
Carrick, H., Holly House, Gateshead-on-Tyne
Carruthers, J. G., Burnbrae House, Milngavie, N.B.
Carter, W. C., 2, Weech Road, Burgess Hill, Hampstead, N.W.
Carteighe, M., 180, New Bond Street, London, W.
Casthélaz, Chas., 19, Rue Ste. Croix de la Bretonnerie, Paris
Castner, Hamilton Y., 23, Cecil Street, Strand, London, W.C.
Cawley, G., 2, Birch Villas, Northern Grove, Didsbury, Manchester
Cawley, J., 278, Passaic Street, Newark, New Jersey, U.S.A.
Chadwick, Edmund, Witton Mill, Blackburn
Chadwick, L. N., Ivy Lawn, Ponders End, Middlesex
Chaloner, G., 35, King's Road, Green Lanes, N.
Chamberlain, J., Gas, Light & Coke Co., Beckton, North Woolwich, E.
Chambers, J. M., Te Mata, Havelock, Hawkes Bay, New Zealand
Chance, A. M., Alkali Works, Oldbury, near Birmingham
Chance, J. F., Alkali Works, Oldbury, near Birmingham
Chandler, Dr. C. F., School of Mines, Columbia College, New York
Chaney, Harry, North Mexican Silver Mining Co., Cusihuiriachic, Chihuahua, Mexico
Chapman, S., 84, Eccleston Square, London, S.W.; and 36, Mark Lane, E.C.
Chapman, W., Crescent Road, Ipswich
Charlton, J., Ellesmere Park, Eccles, near Manchester
Charlton, J., c/o Levinstein & Campbell, 25, New Chambers Street, New York, U.S.A.
Cheesman, A., Bedford Road Brewery, Luton, Beds.
Cheesman, W., c/o F. Kendall & Son, Chemical Works, Stratford-on-Avon
Cheetham, F. W., Carlton Bank, Hyde, Manchester
Cheyne, A. M., c/o Messrs. Burgoyne, 16, Coleman Street, London, E.C.
Chidley, J. R., Abbey Mills Distillery, West Ham, Essex
Chisholm, M. E., 8, Kennington Park Road, London, S.E.
Christie, J., Messrs. John Orr-Ewing & Co., Alexandria Works, Dumbartonshire
Christie, W., 222, Brunswick Road, Bromley, E.
Christopher, G., 8, Rectory Grove, Clapham, London, S.W.
Christy, Thos., Malvern House, Sydenham, S.E.; and 155, Fenchurch Street, London, E.C.
Chrystal, W. J., Shawfield Works, Rutherglen, near Glasgow
Chubb, Harry, 21, Lansdowne Place, Brighton
Church, A. H., Shelsley, Kew, Surrey
Claisen, L., 36, Gereonstrasse, Coln-am-Rhein, Germany
Clanahan, H. C., 88, King Street, Manchester
Clark, E. B., Rangoon Oil Co., Rangoon, Burmah
Clark, J., 138, Bath Street, Glasgow
Clark, H. G. D., Brewery, Twickenham, Middlesex
Clark, R. Ingham, 2, Park Prospect, Queen Anne's Gate, Westminster, S.W.
Clarke, Arthur, St. Ann's Hill Factory, Nottingham
Claudet, A. C., 6, Coleman Street, London, E.C.
Claudet, F. G., The Grange, Weston, near Runcorn
Claus, C., 24, Merton Road, South Wimbledon, S.W.
Claus, Carl F., jun., 9, Nassington Road, Hampstead, N.W.
Clayton, E. G., Chemical Laboratory, 54, Holborn Viaduct, London, E.C.
Clayton, F. C., 18, St. James' Road, Edgbaston, Birmingham
Clemes, J. H., Penrhyn Lodge, Woodbury Down, Finsbury Park, N.
Cleminshaw, E., Windsor Street Gasworks, Birmingham
Clemons, G. H., Cudbear Street, Hunslet Road, Leeds
Clerk, Dugald, c/o Messrs. Tangye's, Limited, Cornwall Works, Birmingham
Cliff, D. Y., 7, Wellington Street, Leeds
Cliff, J., Nesbitt Hall, Fulneck, Leeds
Cliff, Stephen, Wortley, near Leeds
Clift, J., Kemp Field House, Knottingley, Yorks.
Clifton, C. D., Royal Oak Brewery, Stockport
Cloud, T. C., Wallaroo Smelting Works, Wallaroo, South Australia
Clowes, F., University College, Nottingham
Clowes, G. A., Needham Market, Suffolk
Coates, John, 106, Cannon Street, London, E.C.
Cobb, F., 79, Cornhill, London, E.C.
Cochrane, Wm. P., Ormesby Ironworks, Middlesbro'; and 3, Belmont Terrace, Coatham, Redcar
Cockburn, J., 11, Heathcote Street, Mecklenburgh Square, London, W.C.
Coghill, P. G., 16, Hornton Street, High Street, Kensington, W.
Cogswell, W. B., Syracuse, New York, U.S.A.
Cohen, J., Beech House, Pendleton, Manchester
Colby, W. H., Oakley, Ruthin Road, Denbigh
Coleman, Jos. B., University College, Nottingham
Coleman, J. J., Ardarroch, Bearsden, near Glasgow
Collens, E., Vinegar Works, Stourport, Worcestershire
Collins, J. H., 64, Bickerton Road, Highgate New Town, London, N.
Collins, John, Bradford Chambers, Mawdsley Street, Bolton-le-Moors
Collins, H. S., Messrs. Langton & Co., 230, Upper Thames Street, London, E.C.
Collyns, C. S. A., 47, Park Street, Greenheys, Manchester
Colson, A., Gas Office, Millstone Lane, Leicester
Connor, C. C., Notting Hill House, Belfast, Ireland
Conrad, E. C., 23, Well Street, Wellclose Square, London, E.
Cook, E. M., 154, East 37th Street, New York, U.S.A.
Cook, E. R., East London Soap Works, Bow, London, E.
Cook, H. J., East London Soap Works, Bow, London, E.
Cook, Robt., Atlas Chemical Works, Widnes
Cooke, Leonard, Horwich Vale, near Bolton-le-Moors
Cooke, Samuel, Poona, Bombay, India
Cookson, N. T., Newcastle-on-Tyne
Coomber, Thos., 9, Osborne Road, Clifton, Bristol
Cooper, A., North-Eastern Steel Co., Middlesbrough-on-Tees; and the Laurels, Linthorpe, near Middlesbrough-on-Tees
Cooper, Claude H., The Towers, Old Sneinton, Nottingham
Cooper, H. P., 15, Haringey Road, Hornsey, N.
Corbett, E., Plaskynaston Chemical Works, Ruabon, North Wales
Corbett, Jno., M.P., Stoke Works, near Bromsgrove, Worcestershire
Cottam, J. C., 39, Lombard Street, London, E.C.
Cottell, O. D., 101, Long Lane, Bermondsey, S.E.
Cotterell, Roeke, 35a, Ann Street, Glasgow
Cotterill, Thos., Lombard Street West, West Bromwich
Cotton, J., Church Street, St. Helens

NOTICES.

Notice is hereby given that the next Annual General Meeting will be held in Manchester in the month of July, 1887, instead of in Glasgow as originally arranged; the Annual General Meeting in Glasgow being postponed until 1888.

This change originated in a generally-expressed desire, resulting in a special invitation from the Manchester Section, supported by the cordial acquiescence of the Glasgow Section. It will enable members to visit both the Jubilee Exhibition in Manchester, and the Glasgow Exhibition of 1888.

Full particulars as to the Manchester Meeting will appear in a subsequent issue.

The supply of copies of the Journal for January, 1882, and January, 1883, being now exhausted, the Secretary would be glad to receive communications from members possessing extra copies of those numbers, in good condition, with a view to purchase.

Should sufficient applications for complete sets be received, the numbers will be reprinted.

Authors of communications read before the Society or any of its Local Sections are requested to take notice that, under Bye-Law 43, they cannot receive the prescribed 50 copies of their communications unless they comply with the condition laid down in that Bye-Law—viz., that they give notice of their desire to receive such copies upon their manuscript before sending it to the Editor. Mention should also be made as to whether the Discussion is to be included in the reprint.

CHANGES OF ADDRESS.

T. T. Best, l/o Wavertree; 4, Markt Platz, Erlangen, Bavaria.

E. N. Butt, l/o Curzon Street; 25, Sussex Gardens, Hyde Park, W.

H. Carrick, l/o Redheugh; Holly House, Gateshead-on-Tyne.

John Craw, l/o Caledonia House; Meadowbank, Greenock Road, Paisley, N.B.

A. R. Davis, l/o Eaglescliffe; 9, Ebor Terrace, Woodhouse Hill, Leeds.

Chas. Estcourt, l/o Princess Street; 20, Albert Square, Manchester.

Wm. Galbraith, l/o Glengarnock; 136, West Graham Street, Glasgow.

R. Gracey, l/o Woodville Terrace; 21, Nile Street, Liverpool.

A. Griffiths, l/o Clyde Cottage; Elmbank, Pleasance, Falkirk, N.B.

B. Hart, l/o Old Charlton; 106, Trinity Street, Norwich.

Joseph Hartley, l/o Longsight; 3, Brook Road, Gorton Hall, near Manchester.

R. C. Heath, l/o Cliff Hill; Myton Grange, near Warwick.

A. F. Hills; Journals to "Library," Thames Ironworks, etc., Co., Victoria Dock Road, E.

W. A. Hills, l/o Chester; Great Barr, near Birmingham.

R. S. Howarth, l/o Elizabeth Street; 21, Bellott Street, Cheetham, Manchester.

W. G. Johnstone, l/o Warrington; Stevens Institute of Technology, Hobokeo, N.J., U.S.A.

Lewis Johnston, l/o Edinburgh; Newbattle Collieries, Dalkeith, N.B.

Jno. Knowles, l/o Brackley Street; 58, Greenway Road, Runcoro.

R. Lucus, l/o Clayton; 10, North Road, Longsight, Manchester.

A. Luck, l/o Stamford Street; Powder Mills, Dartford, Kent.

J. S. Macarthur, l/o Glasgow; Cassel Gold Extracting Co., Limited, 13, West Scotland Street, Kinning Park, Glasgow.

A. D. Markham, l/o Trinity Square; 18, Merrick Square, Trinity Street, Borough, S.E.

G. D. Mease, l/o Montrell Road; 23, Killieser Avenue, Telford Park, S.W.

J. W. Mitchell, l/o Prospect Hill; 63, Burnley Road, Rawtenstall.

Lock Moore, l/o Nottingham; 28, St. Clair Street, Rochester N.Y., U.S.A.

Jas. Napier, jun. l/o Camlachie; 10, Carment Drive, Shawlands, Glasgow.

Jno. Patterson, l/o Derwent Villa; Hawthorne Terrace, Workington, Cumberland.

H. Peachey, l/o Chichester; Circus Brewery, Shrewsbury.

Jno. Ruffle, l/o Upton Manor; Portway House, Plashet Road, Plaistow, E.

E. Sainsbury, l/o Dunster House; Briton Ferry Chemical Works, Glamorganshire.

D. Stewart, l/o Milton of Campsie; Birdston Farm, Kirkintilloch, N.B.

F. Napier Sutton, l/o Beckenham; 57, Gordon Square, London, W.C.

Thos. Warne, l/o Wednesbury; 60, Westbourne Street, Walsall.

S. G. Webb, l/o Plymouth; c/o W. Pilkington & Son, Widnes.

H. E. Wilmot, l/o Westbourne Park; 27, Upper Berkeley Street, London, W.

P. B. Womersley, l/o West Ham; Lynmead, Wanstead, Essex.

J. C. Wright; Journals to 11, Cargo Fleet Road, Middlesborough.

Jno. Young, l/o Milton of Campsie; 22, Belhaven Terrace, Kelvinside, Glasgow.

T. Graham Young, l/o Limefield; Westfield, West Calder, N.B.

W. Zinkeisen, l/o Glasgow; c/o Frau Heléne Fischer, Rappstrasse, No. 3, Tubingen, Germany.

CHANGES OF ADDRESS REQUIRED.

H. A. Lawrance, l/o Bramshill Villas, Harlesden, N.W.
G. B. Nicoll, l/o Millbrook, near Devonport.
S. Sellon, l/o Palace Club, Westminster.
A. A. Tunbridge, l/o The Crescent, Leicester.

LIST OF MEMBERS ELECTED, 21st JANUARY, 1887.

H. Auer, Lathom House, Halebank, near Widnes, chemist.

Jos. Barrow, Oldham Road, Failsworth, Manchester, assistant chemist.

J. Ralston Bell, Appleby Iron Co., Frodingham, Doncaster, chemist.

Jno. Bell, Millburn, Renfrew, N.B., dyer.

Peter Boa, 119, George Street, Edinburgh, chemist and druggist.

M. Bythway, 43, Lloyd Street, Albert Square, Manchester, drysalter.

F. W. Cheetham, Great Norbury Street, Hyde, Manchester, hat manufacturer.

Percy de G. Coghill, 16, Hornton street, High Street, Kensington, W., works chemist.

G. M. Cruickshank, 62, St. Vincent Street, Glasgow, consulting engineer and patent agent.

Wm. Cuthbertson, Caroline Park, Edinburgh, chemical manufacturer.

G. Davidson, c/o W. & H. M. Goulding, Limited, The Glen, Cork, chemist.

Wm. Duckworth, 93, Corporation Street, Manchester, Manufacturing chemist.

Robert Haig, Busby Printworks, Glasgow, chemist.

Jas. C. Hamilton, Kingscavil, Linlithgow, N.B., works manager.

Wm. P. Hatton, 13, St. Quintin Avenue, North Kensington, W., assistant starch manufacturer.

Y. Kitamura, c/o Mr. Goto, 12, Chitosecho, Honyo, Tokyo, Japan, agricultural chemist.

C. W. Lowe, Summerfield House, Reddish, near Stockport, chemical student.

R. C. Maclagan, M.D., 5, Coates Crescent, Edinburgh, ink manufacturer.

Wm. Marriott, 8, Belgrave Terrace, Huddersfield, manufacturing chemist.

Emile Miest, Ste. Marie d'Oignies, par Tamines, Belgium, engineer.

Wm Bailey Moore, Cauldon House, Shelton, Stoke-on-Trent, porcelain manufacturer.

Giuseppe Moretti, via Cerretani, 8, Firenze, Italy, soap and oil manufacturer.

F. Nettlefold, The Explosives Co., Stowmarket, chemist.

T. Chalkley Palmer, 22, North Front Street, Philadelphia, Pa., U.S.A., chemist.

Jno. V. Pegge, c/o Nunneley & Co., Bridge Street Brewery, Burton-on-Trent, brewer.

Dr. Jos. Petraczek, c/o Read, Holliday & Sons, Huddersfield, technical chemist.

J. G. Ross, 14, Argyle Place, Edinburgh, analyst.

Edgar F. Smith, Wittenberg College, Springfield, Ohio, U.S.A., professor of chemistry.

A. E. Tanner, High Cross, Tottenham, N., pharmaceutical chemist.

S. Tsukiyama, Imperial Paper Mills, Oji, Tokyo, Japan, chemist.

Dr. R. Turgenseo, Oberroblingen a See, bei Halle, Germany.

Cornelius Walton, 63, Queen Victoria Street, London, E.C., engineer.

S. J. White, 3329, Powelton Avenue, Philadelphia, Pa., U.S.A., chemical student.

W. Collingwood Williams, 86, Grove Street, Liverpool, analyst.

Deaths.

Col. Sir Francis Bolton, 19, Grosvenor Gardens, London, S.W.—at Bournemouth, January 5.

M. G. Crossman, Berwick-on-Tweed.

Emile Leroy, Directeur de la Soudière, Cie. de St. Gobain, Chauny, Aisne, France—December 19.

London Section.

CHEMICAL SOCIETY'S ROOMS, BURLINGTON HOUSE.

Chairman: David Howard.

Committee:

Sir F. A. Abel.
H. E. Armstrong.
W. Lant Carpenter.
W. Crowder.
C. Graham.
S. Hall.
A. K. Huntington.
R. Messel.
R. E. R. Newlands.
B. Redwood.
T. Royle.
John Spiller.
G. C. Trewby.
J. Williams.

Hon. Local Sec. and Treasurer: Thos. Tyrer,
Garden Wharf, Church Road, Battersea, S.W.

The meetings of the London Section will be held on the first Monday in each month.

SESSION 1886—87.

Prospective Arrangements.

Feb. 7.—Mr. W. Jago, "On Fermentation in its relation to Bread Making."
,, Mr. J. Mactear, "A New Method of Elevating Liquids, especially applicable to Acids."
,, Mr. C. Napier Hake, "Notes on the Stassfurth Industries."
,, Mr. Wingham, "English-grown Tobacco."
March 7.—Messrs. Cross and Bevan, "Mr. Hermite's Method of Electrolytic Bleaching."
,, Mr. J. Mactear, "The Castner Process for Production of Sodium."
April 4.—Triennial Election of Sectional Officers and Committee.

Notices of Meetings and Papers will be found in the Scientific Journals.

Notices of papers and communications to be made to the Local Secretary.

ON KINETITE.

BY WATSON SMITH, F.C.S., F.I.C.,

Lecturer in Chemical Technology in the Victoria University, etc.

THERE is no doubt, I think, that any new blasting explosive for which it can be truly claimed that it is so easy to prepare and mix, and withal so safe, that its principal constituents might be readily and safely transported to the place where they are wanted, and the composition there made up,—or, that if first made and then carried as a whole to its destination, there is not the slightest peril from exudation of dangerous liquid matters, or, in fact, danger of any kind of mechanical separation; moreover, that supposing by violent percussion at any point, some of the explosive lying about be detonated at that point, the detonation confines itself to the said fragment immediately struck, and does not spread to the surrounding substance—then, other things being equal, such new explosive is, I conceive, well worthy of as large a share of confidence as can be given to such matters. This certainly becomes the case if we can say of it that practically in open spaces it can scarcely be called an explosive, and is thus harmless; that it does not even burn very readily or quickly in contact with a flame, and that it remains unchanged on keeping, whether in hot or cold weather. But most of these advantages were claimed. and so far as my experience has gone, rightly claimed, for certain members of precisely the class of explosives to which kinetite, the subject of my paper, belongs, so far back as 1873, in a remarkable paper read before the Chemical Society by Dr. Hermann Sprengel. This paper was termed by Sir Frederick Abel, in his presidential address before our Society in 1883, "one of the most interesting, original, and suggestive of comparatively recent contributions to the literature of explosives," and I may now add that it seems to me it has proved sufficiently suggestive to the inventors of *Kinetite* to have enabled them by the addition of a certain improvement to make what I cannot help regarding as the safest blasting explosive in existence. Of Dr. Sprengel's paper (*J. Chem. Soc.* 1873, pages 805 and 806), Sir Frederick Abel in his address (this Journal, vol. ii. pages 312 and 313) gave an abstract, which I beg herewith to reproduce, since it so felicitously condenses into a very brief space so much that was important in that and previous papers:—

"In a memoir contributed to the Chemical Society in 1873, Dr. Hermann Sprengel sets forth the reasoning whereby he was led in 1871 and subsequently to make a series of experiments demonstrating that mixtures of strong nitric acid (sp. gr. 1·5) with solid or liquid hydrocarbons, such as naphthalene, phenol, or benzene, or with other very readily oxidisable liquids, such as carbon bisulphide, may be detonated, and that potassium chlorate may be also applied in the same way in conjunction with such substances, so that cylinders of compressed chlorate might be converted at any time into explosive cartridges by saturating them with the sulphide or with a liquid hydrocarbon. He pointed out that one obstacle to the practical application of mixtures of nitric acid and hydrocarbons—namely, the heat developed upon producing the mixture, due to the nitrification which ensues (and very prone to establish violent oxidation and even ignition)—may be removed by employing the *nitro-products* instead of the original hydrocarbons. Thus, while the addition of strong nitric acid to phenol would inflame it, the employment of trinitro phenol would actually give rise to a very considerable depression of temperature on mixing with nitric acid. And again, the employment of nitrobenzene would be attended only by a trifling elevation of temperature, while cold would be produced by using dinitrobenzene. Sprengel urged that the facts brought forward by him were susceptible of important application, because powerful explosive cartridges or charges might at any time be rapidly prepared from two ingredients which, kept separately, are non-explosive."

I shall now try to show that the so-called kinetite is virtually one of what Dr. Sprengel terms his "safety explosives" (see this Journal, 1886, page 200), and by a modification and improvement wrought by Messrs. T. Petry, O. Fallenstein, and H. Lisch, of Düren, the safety is somewhat further enhanced by a greater convenience of form safely conferred upon the nitrobenzene used, that liquid being converted into a jelly that can easily be packed, carried, or stored with safety, and without danger of exudation. Let us first see what kinetite exactly is. Messrs. Petry, Fallenstein and Lisch (Ger. Pat. 31,786, June 18, 1884) prepare this explosive by dissolving guncotton, or other nitrocellulose, in the nitro-compound of an aromatic hydrocarbon,—for example, nitrobenzene,—and then they knead into the resulting jelly, potassium chlorate, nitrate, ammonium nitrate, and similar compounds, and finally add to the whole mass and incorporate with it three per cent. of antimony pentasulphide. It is proposed that from this explosive, as with dynamite, cartridges enveloped in paper cases should be formed. These kinetite cartridges have been manufactured by the firm of Petry & Fallenstein, of Duren, since 1884. Some coal-mining experiments were tried with these cartridges in 1884 near Stolberg, and a full account is given in the *Berg und Hüttenmännischen Zeitung* for 1885, page 65.

The results of these experiments, tabulated as follows:— show that kinetite, as regards consumption and cost, did not altogether compare very favourably with gunpowder and dynamite, but in the displacement of material in the working of seams, it appears to slightly better advantage even than dynamite. In the article on these experiments—*Dingl. Polyt. J.* **256**, 409 (*i.e.*, in 1884)—it is very truly added that first experiments of this kind do not warrant the drawing of conclusions, and that "it is probable the correct method of using kinetite has not been found out":—

		Consumption in kilos. for one metre.	Costs per metre.	Metres thrown up in seam working.
In field-work with	Gunpowder (70 per cent.)	6·85	4·57	0·046
	Dynamite	3·54	7·70	0·051
	Kinetite	4·30	9·82	0·053
In shaft-sinking with	Dynamite	5·20	13·63	0·0129
	Kinetite	8·27	22·36	0·0135

(Presumably the metres above referred to are cubic metres.)

"The kinetite used in the experiments referred to was made of gun-cotton (probably dinitro-cellulose) and nitrobenzene made into a jelly, in which potassium chlorate and nitrate were kneaded, and to which some antimony pentasulphide was added It is stated that kinetite in spite of this latter addition is nevertheless difficult to explode, and can only be brought to this by very strong detonating caps. It is, however, waterproof, and cannot be frozen. It requires a good solid tamping, a circumstance which becomes important in actual working, and dangerous with detonating caps. Experiments in which stoppers of gypsum or hay were used seemed to answer well. The only obstacle to the use of kinetite is said to be the circumstance that its production is dearer than that of blasting-gelatin or dynamite."

It must be remembered, however, that this was written (1884) when benzene commanded a market price of some five to six shillings per gallon; now the price is 1s. 4d. to 1s. 6d. per gallon. The preparation of kinetite has been patented in this country as a communication from Messrs. Petry & Fallenstein to Thomas Wilkins, of Peckham, Surrey (Eng. Pat. 10,986, August 6, 1884).

In this patent the advantages claimed for kinetite are that "whilst it is stronger than ordinary gunpowder (explosive force five or six times that of ordinary powder), it is far less dangerous than dynamite, and being very easily mixed, and that mixing being unattended with danger, the ingredients (none of which are *per se* explosive, except the small percentage of gun-cotton) may be transported to the place where an explosive is required and there mixed. Moreover the compound of gun-cotton and nitrobenzene is a non-explosive gelatinous mass; hence the gun-cotton can be dissolved before transport to form the jelly, and all danger to the public from the carriage of explosives for mining purposes suppressed."

The explosive itself is a plastic mass varying in consistence according to the mixture adopted, and the proportions recommended as giving the best results are the following:—

	Per cent.
Nitrobenzene (or similar nitro-compounds)	16 to 21
Gun-cotton (or other form of nitro-cellulose) ..	¾ to 1
Alkaline chlorates and nitrates	75 to 82¼
Sulphur, as antimony pentasulphide (or other sulphide)	1 to 3
	100 100

The above are the English patentee's own words. Now let us hear the results obtained by German authorities not interested in anything but the actual truth and their own personal reputation.

In the first place, here is the translation I have made of the original of a stamped testimonial from the Bürgermeister of the locality where the works of Messrs. Petry & Fallenstein stands:—

Herewith it is testified that in the Blasting Explosive Works for Kinetite manufacture, owned by Messrs. Petry & Fallenstein, licensed in August 26, 1884, no accident or mishap of any kind has occurred.

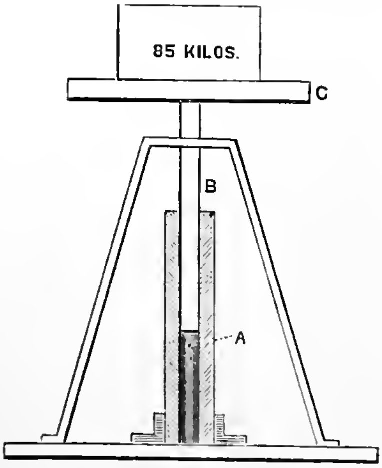
K. K., Bürgermeisterei Amt.

Rolsdorf, June 27, 1885.

Next follows a translation of a report, manuscript copy of which has been sent me. This report deals with the question as to the SENSITIVENESS of kinetite, and runs as follows:—

At the request of General Director Landsberg of Aachen, in presence of Director Blum and also Mining Director Dunkel of the Coal Mine Diepenlinchen, near Stolberg, the following experiments were tried—

The iron tube A shown in the adjoining cut serves for the reception of the cartridge, and the iron ramrod B is furnished with a plate C for carrying the weight, whereby the pressure required in ramming a bore-hole can be given: A was loaded with a cartridge of kinetite, the ramrod B adjusted, and its plate C laden with an 85kilo. weight.



Then the plate C, and with it the ramrod B, was set rotating in order to produce friction. The cartridge in the tube was now exposed to a violent concussive friction by allowing a weight of 21kilos. to fall repeatedly from a height of one metre upon the ramrod. Neither by this means nor in the foregoing cases did either ignition or explosion of the kinetite result. By the blows of the ramrod, however, the latter was so firmly imbedded in the kinetite that it was possible to lift the whole apparatus up by the ramrod without getting the latter loose. At last the tube was unscrewed out of the apparatus, when it was found that the kinetite was pressed extremely hard on the bottom. It was ignited and burned slowly without the slightest appearance of explosion.

The General Director Landsberg declared himself completely satisfied, by the result of these trials, as to the safety of kinetite as a blasting explosive.

I have also received copy of another manuscript report from Germany, containing the report of other experiments of which I will give a condensed account.

FIG. 1.

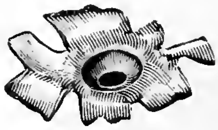


FIG. 3.—View from above of piece of Cylinder.

FIG. 2.—Side View.

On April 2, 1885, before the Königl. Bergrath Wagner, in presence of Bergassessors Müller and Kropp, Professor Schulz, with Messrs. Till, Baumann, Zimmermann and Hillonblink, engineers and managers, the following trials were made. A fire was kindled on a hearth over which was an arch in which a hole had been made admitting a funnel. It was so contrived that cartridges, etc., could be arranged in the space between the funnel and an iron cap which covered the funnel. This cap could be raised by a string, and in so doing, the cartridges and other matters in the space between funnel and cap were precipitated through the funnel and upon the grate or hearth. The kinetite cartridges from Petry & Fallenstein's works weighed 80grms. each. The results were briefly as follows:—

(1.) Two kinetite cartridges cut into four equal parts and distributed in the funnel. *No explosion.*

(2.) A kinetite cartridge tightly wrapped in a thick paper covering 74cm. long, in order to exert pressure. *No explosion.*

(3.) Two kinetite cartridges pressed together in a strong bedding-mould. *No explosion.*

(4.) Three percussion caps (such as are used for dynamite) were completely enveloped in a kinetite cartridge, and strongly bound up in paper. *Only explosion of the detonating caps and combustion of the cartridge.*

Thrown upon a burning fire it thus appears that kinetite cartridges cannot produce an explosion.

The Royal Mining Councillor Wagner testifies, under his seal, that the results of these experiments precisely coincide with those he had himself obtained in similar trials.

I have obtained also a translation of the Report of the Royal Technical and Administrative Military Committee in Vienna on a sample of so-called

"Petrofracteur," submitted in order to procure licence for manufacturing. Petrofracteur generally resembles kinetite in composition, but differs specially in that it contains no guncotton, which renders the nitrobenzene of the jelly more difficult of volatilisation.

Petrofracteur consists of a mixture of the following substances in the following proportions:—10 per cent. nitrobenzene, 67 per cent. potassium chlorate, 20 per cent. potassium nitrate, and three per cent. antimony pentasulphide. With the powder test of Nebatius it was found impossible to explode the triturated sample with double-filled sporting caps, and hence petrofracteur is unsuitable for gunnery purposes.

With an adaptation of the Brisanz-meter, using lead cylinders and an adjustable ballistic pendulum, 17grms. of petrofracteur gave a pendulum propulsion of 1·98°, 2·43°, 1·88°; average = 2·11°, as against 8·76 of 70 per cent. Kieselguhr dynamite, and a compression of the lead cylinders, each 20mm. long, of 1·00, 1·500, 1·10; average = 1·20 kilogram-meters, as against 11·9 kilogram-meters of 70 per cent. dynamite.

Detonated in the open, petrofracteur is therefore far less effective than 70 per cent. dynamite. Exposed in the open air for eight days it lost 9·73 per cent. of its weight, due to the volatilisation of the nitrobenzene, and an impervious casing is recommended. In damp air it loses nitrobenzene, but absorbs moisture. Heated to 70° C. for a lengthened period, after 2—3 days all nitrobenzene is lost, but no further decomposition was observable. Heated in a closed "eprouvette" to 70° C. the nitrobenzene evaporated, and the preparation after two days became deep black by the change of the antimony pentasulphide into the lower black sulphide and sulphur. Neither explosion, ignition, nor tumultuous decomposition takes place. The substance is not affected by temperatures near or below zero. Slowly heating from 70° upwards causes no explosion. At 340° it commences to melt and then decomposes, leaving a white residue. The fusion and decomposition are accompanied with pulling and spitting on suddenly heating to 500°, and combustion takes place. A coating of 1mm. thick between steel surfaces of 1·34sq.c.m. area, the preparation only exploded by blows of 4 kilogram-meters and upwards upon the first blow, below this down to 3·5 kilogram-meters only partially, and below the latter not at all, whilst 70 per cent. Kieselguhr dynamite explodes with 1·5 kilogram-meters.

The Committee considers petrofracteur less dangerous than Kieselguhr dynamite, with respect to personal and public safety, as regards its manufacture, storage, packing, conveyance generally, and particularly railway conveyance, also in respect to its sale and use no objections whatever stand in its way.

On comparison of this report with the foregoing on kinetite, it is observable that petrofracteur is the more sensitive of the two, and not a little so. I am sure, moreover, that kinetite suddenly heated to 500° would not break into combustion. On referring to the constituents of both explosives, generally so similar, and to the proportions adopted, I am led to the conclusion that the difference referred to is due to the larger proportion of antimony pentasulphide combined with the greater inequality of the mixture with liquid nitrobenzene, and also to what we may call the superior wetting power of the nitrobenzene—*i.e.*, its closer physical contact with the solid constituents of the "petrofracteur" mixture, whereas in kinetite the nitrobenzene-guncotton jelly envelops each grain of saline matter with a waterproof and airproof skin, which does not, I believe, creep into pores or minute crevices, but roughly envelops each minute grain. Thus, I believe what the kinetite slightly gains in a kind of theoretical way by the addition of its small $\frac{3}{4}$ to 1 per cent. of gun-cotton, in explosive power, it very largely gains in the physical condition into which it and the nitrobenzene are thrown, as a jelly, and in the whole physical condition so largely out of proportion to the minute quantity of nitrocellulose required, conferred thus upon the entire mass.

You may now naturally inquire: "Since the manufacture of kinetite has been patented in this country by Wilkins, it is to be presumed efforts have been made to obtain a licence for the manufacture?" This is so: nevertheless no success has attended these efforts, the company desiring to commence the manufacture failing to convince the Secretary of State of the sufficient safety of the explosive in question; but being desirous of obtaining further tests, proofs, etc., it then invited further and more searching trials, and for this purpose exhaustive experiments and reports have been made separately and independently by Prof. Stahlschmidt of the Polytechnic Schools in Aachen, by Prof. Lunge, of Zürich, by Professor J. Campbell Brown, of Liverpool, and by myself. Prof. Campbell Brown and I worked together with regard to one point—viz., experiments as to the effect of a glancing blow, wood on wood. Before saying anything as to the experiments thus more recently tried, I must refer to the Government report, which is adverse to kinetite.

In the recently published Blue Book, the Tenth Annual Report of Her Majesty's Inspectors of Explosives—viz., that for the year 1885, pages 30 and 31, the following report appears as to kinetite:—

> Kinetite consists of nitrobenzene thickened or gelatinised by the addition of some collodion cotton incorporated with finely-ground chlorate of potassium and precipitated sulphide of antimony. Nitrobenzene is not present in any of the explosives at present licensed, and kinetite constitutes in some measure a new departure. In some respects, such as the very high temperature required for its ignition and the great difficulty, practically the impossibility, to explode it when unconfined by the application of heat, kinetite possesses considerable advantages, but it suffered under two fatal defects. In the first place it proved to be extremely sensitive to combined friction and percussion, and in the second place it gave indication of a certain want of chemical stability, which, under favourable conditions, might lead to spontaneous ignition or explosion. In regard to the latter point, I [the chemical adviser of the Government] have quite recently received information fully bearing out the correctness of my conclusion: cases of spontaneous ignition of kinetite have not only been actually observed to occur in the laboratory, but in one case, at least, the contents of a magazine containing kinetite were burnt, owing to the spontaneous ignition of the explosives. In the latter case it had been observed that the kinetite had become strongly acid, and arrangements were at once made for its destruction, but the kinetite took fire spontaneously before these arrangements could be carried into effect.
>
> In connection with the rejection of Turpin's explosives, of etnite and of kinetite, all of which contain chlorate of potassium, I should like to offer the following remarks: Chlorate of potassium, on account of the readiness with which it lends itself to the production of powerful explosives, offers a great temptation to inventors of new explosives, and many attempts have been made to put it to practical use, but so far with very limited success only. This is chiefly owing to two causes. In the first place chlorate of potassium is a very unstable compound—it is one of those compounds during the decomposition of which heat is evolved, or energy is produced during decomposition, instead of, as is usually the case, being absorbed, and all such compounds are unstable—and is liable to suffer decomposition under a variety of circumstances, and under, comparatively speaking, slight causes, chemical and mechanical. All chlorate mixtures are liable to what is termed spontaneous ignition or explosion in the presence of a variety of materials, more particularly of such as are acid or are liable to generate acid; and all chlorate mixtures are readily exploded by percussion, but more particularly by combined friction and percussion, such as a glancing

blow, which might easily, and would often, occur in charging a hole. In the second place, there is some evidence to show that this sensitiveness to percussion and friction increases by keeping, more especially if the explosive is exposed to the action of moist and dry air alternately. If inventors would only keep these characteristics of chlorate mixtures in mind they would frequently save themselves serious disappointment.

With respect to the question of stability, Professor Stahlschmidt, in letters addressed to Messrs. Petry & Fallenstein, of which I have translation-copies, makes statements of which I give the following extracts:—

> Neither chlorate of potash, nor saltpetre, nor pentanitrocellulose, nor nitrobenzene, are bodies which either by themselves or in mixture undergo alteration. I have still in my possession a cartridge remaining over from the tests, which has in no wise changed its characteristics, but, on the contrary, retains all the features presented in a perfectly fresh state.

The letter is dated June 14, 1885, and the sample was given to Dr. Stahlschmidt on Dec. 20, 1884. Another letter to Messrs. Petry & Fallenstein, bearing date of Aug. 1, 1885, runs as follows:—

> With respect to the explosiveness of your kinetite by a sliding blow, or a glancing blow, I beg to say that exhaustive trials which I have carried out prove that only very small particles of the explosive compound can be made to explode by this action; in fact, only such particles as are immediately struck. All the rest remained unconsumed, and in part strewn about. Any danger, therefore, of a more extensive explosion taking place is *completely* excluded.

Now, to my mind, only one cause of acidity developing in kinetite is conceivable—viz., the impurity of some of the raw materials, which conceivably might contain a little acid—*e.g.*, the guncotton, the nitrobenzene, and the antimony-pentasulphide. In the latter case, the acidity could scarcely be said to develop; but if not carefully made, the antimony-pentasulphide might of course contain some free sulphur, and this might commence an action. Nevertheless, the proportion of the sulphide used is very small (about 2 per cent.). I cannot but think, in view of the experiments and reports from Germany, as well as those I have tried, that the cases of spontaneous ignition must have arisen from extraordinary causes of impurity, or acids present in the materials, and such mishaps are as liable to arise in many other licensed explosives.

Since kinetite made with the addition of antimony-pentasulphide was rejected by the Secretary of State, the attempt was made to meet his views by removing the sulphide from the mixture; in short, kinetite was made of nitrobenzene jelly and potassium chlorate, with or without the addition of some nitre (6 per cent.). But, thus made, we at once recognise in kinetite a modified form of Sprengel's "rack-a-rock"; still, it no doubt is a modified form, and I believe the physical change induced in the nitrobenzene by dissolving in it so small a quantity of nitrocellulose, forms a distinctly new departure. The experiments made by Lunge, Campbell Brown and myself, were with this modified kinetite. Nevertheless, after our experiments were concluded, the "Potentite" Company, Limited, the company desirous of working Wilkins' patent (the communication from Petry & Fallenstein), received a letter from the Home Office, once more denying the desired licence. The letter ran as follows, and was addressed to Mr. Macan, the London representative of the company:—

WHITEHALL, February 25, 1886.

SIR,—I am directed by the Secretary of State to inform you, with reference to previous correspondence, that the sample of the explosive kinetite submitted by you for examination, although a trifle less sensitive than the sample previously submitted, and rejected, when tested by a glancing blow, is, nevertheless, far too sensitive under this test to admit of its being licensed for general use. I am to state that it has been found that the explosive may be fired without much difficulty by a slight glancing blow from a wooden broomstick, or small mallet, even when placed on a new, or rather soft deal floor, and that, in these circumstances, the Secretary of State has no choice but to refuse to license it.—I am, Sir, your obedient Servant, PEMBERTON.

If I was asked, "What then would be the effect of detonating the portion struck by a mallet or broomstick on a wooden floor, supposing that floor entirely covered with, say a quarter-of-an-inch deep of kinetite? Would it not be an awful explosion?" By no means so; and from an intimate experience with laboratory specimens of kinetite, extending over a year-and-a-half, I can affirm my willingness to allow myself to be placed in such a room, and, if merely furnished with a bucket or two of water, I will undertake to detonate on iron, with an iron hammer, some of the kinetite which shall be in direct contact with all the rest on the floor (to detonate with wood on wood is far too troublesome, and I have often exhausted myself with violent glancing blows ere I could get satisfactory detonations). Nitrobenzene is considerably heavier than water, and so an effusion of water would soon extinguish it on burning, and all that the detonation of the portion struck in a room like that named could do, would be to inflame the oil in the surrounding kinetite; and yet in none of the trials I have made or seen made have I ever seen kinetite set on fire by the detonation of a part of it. A striking experiment performed at Melling, near Liverpool, in the presence of Prof. Campbell Brown and myself, and to be subsequently described, will justify, I believe, what may at first seem to look like a suicidal proposition on my part.

I will now give the report of Prof. Lunge on experiments he made with kinetite free from sulphides, and which he himself prepared from the gelatin supplied to him by Messrs. Petry & Fallenstein:—

[TRANSLATION COPY.]

ZÜRICH, 1st October, 1885.

REPORT UPON THE KINETITE OF PETRY & FALLENSTEIN, OF DUREN.

I have been requested by the above firm to report upon the chemical stability of their patented explosive, called kinetite; as also upon its sensitiveness against shock and blow. To this end, the said firm placed at my disposal a quantity of gelatine, composed of 5 parts of nitrocellulose and 100 parts of nitrobenzol, and with this I myself prepared the explosive compound, according to the directions of the patent, by mixing 22 parts of this gelatine with a compound of 72 parts of chlorate of potash, and 6 parts of nitrate of potash, both finely powdered and intimately kneaded together, until a homogeneous mass was obtained, in which each salt particle was coated or covered by the nitrobenzol gelatine. The mass thus acquired a consistency of about that of damp garden mould, and obtained also a certain although low grade of plasticity.

With kinetite thus prepared, I have carried out the following experiments:—

I.—BEHAVIOUR UNDER SHOCK OR BLOW.

1. A small quantity of kinetite was spread out upon cardboard, and laid upon an iron anvil. Violent blows with a hammer were then dealt upon it, without, however, producing any explosion. The same conditions obtained with wood.

2. Some kinetite was next placed upon a thin sheet of copper-plate, and laid together with it on the anvil.

Here, too, on being struck violently with a hammer, no explosions resulted. The kinetite was merely flattened out, and stuck firmly to the under (striking) surface of the hammer.

3. Kinetite, laid directly upon the iron anvil, exploded on being struck with the hammer, but only in so far as it came immediately between the two iron (steel) surfaces. All the rest was merely compressed, or scattered about. So, for instance, a portion of kinetite remained sticking to the surface of the hammer head unchanged, and was finally brought to explosion by a somewhat altered direction given to the blow.

Inference.

Kinetite only explodes, even by violent blows and shocks, when iron impinges direct on iron. Between iron and copper it cannot be brought to explode; and equally so between iron or cardboard or wood.

[*] Kinetite, therefore, is as little sensitive to shock or blow as any other known well-behaved explosive.

II.—BEHAVIOUR UNDER IGNITION.

Even larger quantities (*i.e.*, as in the case of my experiments, several grammes) of kinetite may be ignited, either by a burning body, or by a red-hot iron, without any appearances of explosion taking place. The compound burns quietly with a strong illumination and sooty flame, and leaves a hard, salt residue.

III.—BEHAVIOUR WHEN HEATED.

1. A few grammes of kinetite were heated in an air bath during a lengthened period to 120° C. (248° F.).

Subjected to this process, the nitrobenzol gradually evaporated. The salty residue showed no explosive qualities.

2. A few grammes of kinetite were directly heated in an enamelled iron dish, over a moderately large gas flame (Bunsen burner). The nitrobenzol evaporated very quickly and completely, but quietly, in the form of a brownish-yellow vapour. A residue of salts remained, which later on was brought to a state of fusion, without, however, obtaining any appearances of explosion.

3. A few grammes were placed in the same dish, but over a very powerful gas-flame, so that a very high temperature was very quickly reached. In about 30 seconds the substance ignited and burned quietly away, leaving a residue of molten salts. The ignition occurred evidently in this instance, by reason of the fact that the temperature was rapidly raised to the point of inflammability before evaporation of the nitrobenzol had taken place.

4. In order to test if, from any cause of separation between the gelatine and the salt molecules, a greater degree of danger would arise, I heated in a water bath a few grammes of the gelatine (*i.e.*, of the compound of 100 nitrobenzole and 5 nitrocellulose) by itself only. As an open dish was used, the temperature did not rise above 80° C. (166° F.). At this temperature, however, it did not by any means reach the point of fusion, but, on the contrary, retained almost the same salve-like condition which it has under ordinary temperatures. It may therefore be confidently assumed that no separation (disincorporation) of the explosive compound from any sweating out of the gelatine—consequent, say, upon the heat of summer weather—can take place. It may also be remarked that the gelatine thus heated in a water bath, on being ignited, burnt quietly away without a trace of explosive characteristics. For itself alone it also evinces, when struck by iron upon iron, much weaker explosive characteristics than kinetite.

Any disincorporation of the compound would therefore *diminish* the danger of carriage and storage. Quite the opposite of ordinary dynamite, which on account of the sweating out of nitro-glycerine in liquid form, increases its dangerousness to an enormous extent.

Inference.

In reference to its behaviour under heating and ignition, kinetite is considerably less dangerous, in respect of carriage and storage, than any other explosive known to me in my general experience hitherto.

IV.—ITS BEHAVIOUR ON PROLONGED STORAGE.

Experiments in respect to this I could not carry out, as a lengthened period of time would be necessary. I consider, however, such experiments quite purposeless. No expert would for a moment entertain the thought that from any degree of prolonged storage, to whatever length of time extended, any such change in the ingredients composing kinetite could take place, which could in any sense make its manipulation in the slightest degree more dangerous.

If the storage vessels are not tight, nitrobenzol will evaporate. If water is permitted to associate with it, the salts will be washed out. In either case the residue will always be *less explosive.*

If stored in vessels impervious to air and water, it is beyond question that any reaction can take place which could increase the danger of explosion, such as is the case with imperfectly purified nitroglycerine, or with dynamite manufactured therefrom.

On the basis of the above facts, and on the basis of the experience which I have had in experimenting, by order of the Swiss Government and Swiss Railways, upon the explosives chiefly used, I give it as my opinion that the explosive called kinetite, manufactured by Petry & Fallenstein, belongs to the least dangerous of all explosives in reference to carriage, manipulation, and storage; and that any possibility of increase of danger, from change of character by storage, or by transport, is entirely excluded.

(Signed) DR. LUNGE,
Professor of Tech. Chemistry
at the Eidgenossischen Polytechnikum,
Zurich.

Prof. J. Campbell Brown's report now follows, and this was written in complete ignorance of Dr. Lunge's experiments, results, or report:—

UNIVERSITY COLLEGE,
LIVERPOOL, 5th Dec., 1885.

I have examined and made experiments with a sample of kinetite received from the Potentite Company, Lim., in November last, and with other samples made by myself, and beg to report as follows:—

1. When submitted to blows upon an iron anvil with an iron hammer, it explodes when struck with sufficient force, but not very easily; and only that portion immediately struck explodes, the surrounding portions, if any, remaining unaltered.

2. When placed upon copper, zinc, and other metals, and struck with an iron hammer, it exploded with greater difficulty and no more completely.

3. It exploded entirely only when placed between two iron plates and struck with a sufficiently heavy hammer.

4. When placed upon wood and struck either directly by the hammer or with the intervention of an iron plate, it only flattened out and did not explode.

5. When placed upon iron, wood, stone, and concrete successively, and struck by a slanting blow of an iron hammer, it behaved in the same way as when struck directly. When struck by a slanting blow of a wooden mallet it did not explode.[†]

6. When placed upon iron, wood, stone, and concrete successively, and struck by a slanting blow of a heavily-shod heel, a small portion only, or sometimes none, exploded, leaving the rest flattened only.

7. When heated in an open dish until half dry, and treated in the same way, it exploded in a similar way—perhaps a little more easily when hot; but when all the nitrobeezene had been evaporated away it did not explode under any kind of blow.

8. When a large quantity is set on fire by any burning substance, or a hot bar, it does not explode, but burns

---

[*] Dr. Lunge here, of course, refers only to direct blows, and not glancing or sliding blows.

[†] More recent experiments by Dr. J. Campbell Brown showed that when fairly beaten into the wood, and continued slanting blows administered till in fact the friction produces warmth, slight detonations could at length be caused, confining themselves, however, to the points and portions struck.—W. S.

quietly away with a smoky flame, leaving a saline mass which contains a little potassium chloride, but chiefly potassium chlorate and nitrate. In one experiment I found as much as half the potassium chlorate reduced to chloride; but in no case was nearly all the chlorate reduced. The residue is non explosive.

9. An ounce of kinetite surrounding one of Geo. Eggerstorff's sextuple detonators and placed on a boulder in the open, did not appear to me to explode when the detonator was fired by a fuse, but was so scattered that no complete evidence as to what became of it could be obtained; the experiment was therefore repeated in the same way, but under an inverted empty barrel. In this case the kinetite was only partly exploded, lifting the head of the barrel, and was partly but imperfectly burnt, there being soot inside the barrel and a strong smell of nitrobenzol on all the grass surrounding the stone on which the kinetite had been placed, and the stone was uninjured.

Judging from all these results, I entertain no doubt whatever that kinetite is a much safer kind of explosive than dynamite and its allies, whether in manufacture, storage, or in use.

J. Campbell Brown, D.Sc.,
Professor of Chemistry in University College, Liverpool, and Victoria University.

As regards my own experiments, I was invited to specially test and report on the chemical stability of kinetite made without antimony pentasulphide, and subsequently with Prof. J. Campbell Brown to witness and to try some field experiments on a larger scale at the Potentite Company's Works and in a neighbouring quarry at Melling, near Liverpool.

Report on the Chemical Stability, etc., of the New Explosive known as "Kinetite."

Oct. 26, 1885.

I. A quantity of kinetite was prepared by me according to the directions furnished, but I took *pure* nitrobenzene instead of the commercial article usually employed. I dissolved 1 part of gun-cotton, the product of the Potentite Company, Melling, by Liverpool, in 20 parts of pure nitrobenzene, prepared specially for me by Mr. C. Dreyfus of the Clayton Aniline Company, near Manchester. I warmed the nitrobenzene in the process of solution, and found that heat causes the gun-cotton to go very quickly into solution. To ascertain if any danger exists in this part of the process by which, with mechanical agitation, no application of heat would be necessary, I heated the mixture to nearly 120° Centigrade (248° F.). The only effect was fuming of the nitrobenzene. Hence, to promote solution of the gun-cotton, warming of the mixture with a closed steam coil would be perfectly and absolutely safe.

My jelly produced as above I now mixed intimately in a porcelain mortar with well-dried potassium chlorate and nitrate, in the following proportions: 22 parts of the aforesaid jelly, 72 parts of chlorate of potassium, and 6 parts nitrate of potassium.

II. I first found that the explosive in portions, each about the size of a pea, was detonated by smart blows with an iron-headed hammer on a cast-iron plate, giving explosions like pistol shots.

III. Similar pieces of explosive (about the consistency of putty) when placed on the iron plate and fired with a lighted match, simply burned with a smoky, luminous flame, quite harmlessly, and left behind a residue of a white saline character. This residue consisted almost entirely of the unaltered potassium chlorate, for it deflagrated powerfully on heating with the blow-pipe flame or charcoal. It is then easy to burn away the nitrobenzene, and probably the gun-cotton, quite harmlessly from the explosive, without sensibly altering the potassium chlorate. I say "without sensibly altering," for, on closely observing the burning mass, I perceived no symptoms of fusing of the residue of chlorate as it was left.

IV. A thin wrought-iron plate was now heated stongly, but not more than to a black heat, and a piece of the explosive was now put on this plate. It commenced to smoke strongly, and continued to do so till the nitrobenzene was volatilised, when intumescence of the chlorate set in with evolution of oxygen gas, as is usual with chlorate of potash when heated—but no sign of *anything approaching* to explosive violence was *at any time* manifested. Neither in III. nor here in IV. does the presence of the gun-cotton manifest itself by any phenomenon in the least degree.

V. Further portions of the explosive were placed in watch-glasses and exposed to temperatures of about 96° to 100° C., and about 70° C. respectively. In from 24 to 30 hours it was found that all nitrobenzene had volatilised, not even the least odour remaining, and residues were left which consisted of chlorate of potassium with the minute quantity of gun-cotton originally added in the form of jelly.

VI. The dry, odourless saline residues obtained by the evaporation of the nitrobenzene were now placed on the cast-iron plate and violently struck with the iron-headed hammer, but without any result in the shape of detonation.

On charcoal with the blow-pipe flame, the chlorate deflagrated and burned along with the gun-cotton in it, but not in the least differently from chlorate of potassium deflagrated alone under the same conditions.

Similar portions of saline residues left as above stated were subjected to the following tests:—

(*a*) Portion placed on a strongly-heated iron plate, quietly fused, evolved oxygen gas just as chlorate of potassium usually does.

(*b*) Another portion refused to ignite, deflagrate, or explode on attempting to fire with the flame of a match.

VII.* A portion kept in a warm room (16° C.) in stoppered bottle for three weeks, was not changed in the least, nor was another portion similarly kept for two months. In fact, in the chemical nature of things, it is quite impossible any spontaneous change should take place.

VIII. Another portion exposed in a watch-glass at about 30° C. for several days, was at the end of about 3½ days found dry, and to consist of a simple mixture of chlorate with the small quantity of gun-cotton of the jelly. The jelly itself I have found perfectly stable, and also that on exposure it does not suffer loss by evaporation of the nitrobenzene like the kinetite, though, of course, such evaporation does take place.

Altogether, I consider the kinetite is *a most safe mixture*, as I believe my experiments amply prove.

IX. The employment of nitrobenzene well washed from *all free acid*, and gun-cotton also free from *acidity*, are precautions which, being very easy of attainment, I see no difficulty or danger at all in the production of kinetite on a large scale, perfectly safe to keep.

X. I have made some kinetite with pure nitrotoluene, and this I find more difficult to detonate than that made with pure nitrobenzene—*i.e.*, a harder blow must be administered. Consequently the use of a commercial benzene containing also toluene, and the resulting employment of a mixture of nitrobenzene and nitrotoluene, offers no risk of danger whatever, but being detonated, even with more difficulty than a kinetite made with pure nitrobenzene, it is, on the contrary, safer.

Watson Smith, F.C.S., F.I.C.,
Lecturer in Chemical Technology in the Victoria University.

Report on a Series of Comparative Experiments made 12th November, 1885, with "Kinetite," "Potentite," and Nobel's Dynamite, at the Works of the Potentite Company, Melling, near Liverpool, in company with Professor J. Campbell Brown, Mr. F. W. Macan, and several Members of the Firm and Officials.

November 20, 1885.

The following experiments were tried with the object

---

* *January* 2, 1887.—A portion of this same sample, and also some of a larger sample prepared from commercial products, and kept since October, 1885, and brought under all normal conditions of exposure, are now perfectly unchanged.

of comparing the explosive effects of the above-named preparations.

Cylinders of solid lead each 2ft. long and 6in. in diameter, were bored with holes down the centre, the bore of each of which is $\frac{15}{16}$ of an inch in diameter, and 18in. in depth. The cartridges were lowered into this tube by the fuse terminated by a detonator inserted in the cartridge, and whilst the end of the fuse projected, the tamping was done with water—*i.e.*, water was poured into the hole until full. The cylinder having been sunk in the earth until only about 4in. projected, the fuse was lighted, and after the explosion the earth was removed and then the tube, when a bulbous swelling was found upon it in the vicinity, more or less, of the cartridge. The volumes of such bulbs could easily be measured by measuring the water capable of filling the cylinders in which the explosions had taken place.

A 1. Two cartridges of potentite (a mixture of nitre and gun-cotton), each weighing 1½oz., were now exploded in a lead cylinder sunk in the earth.

The side of the cylinder was blown out and a rent made, a bulbous bulging out of the lead all round the place where the cartridges were, appearing.

A 2. Two cartridges of potentite, as before, exploded.

Bulging again as before, but no rent; still the bulb contained several cracks and small ruptures.

B 1. Two cartridges of kinetite, of 1½oz. each, exploded as in A 1, and 2. Explosion sharper than in A 1 and 2. But though bulged in a very even bulbous form, not any rupture had taken place.

B 2. Kinetite paste used this time, and not cartridges, the weight employed being the same as in B 1. Sharp report and red flash. Bulb very evenly bulbous in shape.

C. Some kinetite paste was now placed on a granite stone connected with detonator and fuse, and fired. From the sound it was judged that only the detonator exploded. At any rate, all was blown away, and no positive proof remained that the kinetite was not exploded. To get such proof—

C 1. Again some kinetite paste was placed with detonator and fuse on the stone, the fuse lighted, and an empty cask placed over the whole, so as to enclose it. On exploding, the head of the cask was blown out, but the rest of the structure remained unhurt.

On examining the grass, a dark circular line was observed just inside the circle described by the rim of the cask, and this was found to be moist with and to smell strongly of nitrobenzene. Thus it is proved that even with a detonator, when fired in the open, or even in a space so much enclosed, either no explosion or only a very partial one ensues.

C 2. A cartridge of potentite fired on the same stone with a detonator and fuse, just as the kinetite was fired (under an inverted cask), was exploded and blew the cask to pieces.

Comparison of Kinetite and Dynamite (Nobel's Cartridges).

I. Lead cylinders, bored precisely as before, were used. One cartridge of Nobel's dynamite (2¼oz.) was exploded. No flash perceived; the cylinder was bulged locally, but unevenly somewhat as in Fig. 1 (*see p. 4*).

II. One cartridge of kinetite (2¼oz.) exploded. Sharp explosion, much sharper than I. No flash perceived, and cylinder bulged apparently to about double the volume of that in I. with the dynamite. The bulge was remarkably even, however.

III. Two cartridges of kinetite (2¼oz.) exploded. Sharp explosion as in II., but louder. Very regular bulge, of larger size than in II., but an almost perfect bulb. No rupture.

IV. Two cartridges of dynamite (2¼oz. each). Flash, and deep hollow detonation or explosion; earth thrown up, and with it the upper half of the lead cylinder, about 6ft. into the air. This part of the lead cylinder had assumed a form like that in Figs. 2 and 3 (*see p. 4*). A hole was found in the ground where the upper part of the cylinder was, and the lower part remained embedded. The hole measured about 2½ft. in diameter.

V. Another explosion, with a similar charge of dynamite as in IV., gave a result singularly like that of IV. in every respect.

VI. Explosion with another double charge of kinetite (two cartridges of 2¼oz. each) produced a result very like that of III.—viz., a singularly even bulge as if a bulb had been blown upon the tube by an experienced glass-blower, but this time there was a rupture, a hole being blown in the side measuring about 3in. by 1¼in.

Thus it appears that a certain degree of reliance could be placed on a rough calculation of the explosive effect of a charge of kinetite, single or if doubled, but no such calculation could be made with regard to dynamite. For, a small charge of dynamite doing less work than a similarly small one of kinetite, actually did when doubled immeasurably more than double the work of the doubled charge of kinetite, and did it after a somewhat eccentric and destructive fashion. The localised character of the violence of the dynamite explosion was well marked.

As regards any attempt at explanation of the at first sight abnormal results of these latter experiments, one theory suggests itself as possibly the most likely.

It was noticed in each case when a rupture was effected in the lead, that the general results indicated a considerably greater destructive action than when no rupture took place.

In experiment I., where no rupture with the single charge of dynamite took place, it is observed how uneven the bulge of the lead was, though not a large bulge by any means. This indicates the certain rupture of the lead with an explosion of *dynamite the equal of which*, generally speaking, with kinetite would not rupture the lead, because being equally exerted in all directions, an even bulge is produced. The uneven character of the bulge caused by the dynamite also throws some light on the extraordinary and eccentric concentration of violence, so to say, with which dynamite acts upon certain points, in given directions, so as to cause what are called destructive *local* action.

The Action of Kinetite in Blasting Rock.

An experiment was tried in a quarry of sandstone near the Potentite Company's Works, and instead of a cartridge simply a piece of kinetite moulded in the hands was used; this was inserted in the bore hole just as a cartridge would be, in it being inserted also the detonator with fuse. The tamping was not carried out at all, the fuse being simply lighted. An explosion followed, which did admirable work in clearing out a large mass of rock, and in large pieces, and generally manifesting an equal all-round action, which must be of the greatest economic value in blasting in either quarries or coal mines. The testimony of the workman in charge was highly in favour of the kinetite as regards the loosening of large pieces, as compared with that of dynamite. A particularly valuable quality of kinetite was shown in the next experiment. A bore hole had been made in the rock at the bottom of a pool of water, and into this a piece of kinetite paste, first moulded in the hand, was inserted by a workman, who bared his arm and reached down to the bottom of the pool for the purpose. Into the middle of the kinetite the detonator was inserted, the end and a few inches of the fuse projecting above the water. On lighting the fuse, at length an explosion followed, showing the waterproof character of the explosive. Nitrobenzene being insoluble in water, protects the particles of otherwise soluble chlorate of potassium, so that the whole remains insoluble and unwetted in the water.

The fact that in so many cases, probably most, cartridges of kinetite are not needed, and that kinetite may be handled in moulding with safety, as it is not noxious like dynamite,* producing the violent headaches following

---

* I am aware that vapours of nitrobenzene in closed spaces act to some extent as a poison, but the conversion into the jelly prevents the vapourisation to a great extent, and hence the poisonous effect, which again is very far below that of nitroglycerin, even supposing work in closed rooms, of which there is no need.—W. S.

contact with that article, is a strong argument in its favour, both on economic as well as sanitary grounds.

WATSON SMITH, F.C.S., F.I.C.,
Lecturer in Chemical Technology in the Victoria University.

As an expression of opinion, the immense preponderance of all the evidence compels me to say, with Professor Lunge, that "the explosive called kinetite belongs to the least dangerous of all explosives in reference to carriage, manipulation and storage."

As regards the use of kinetite in coal mines, I have heard a report from Germany, the reference to which I can unfortunately not find again, that it behaves exceedingly well, especially in detaching or loosening very large masses and making but little smalls and dust. This is a matter of immense importance in coal mining.

In conclusion, permit me to say that I have not the slightest interest in kinetite beyond my reputation as a representative of chemical technology, and my duty as regards my experiments and report, which, again, the company charged me to make in their interests, with the most unbiased intent to elicit the full truth, and I must confess that in those interests, those of my country, and with every due care to my own reputation, I cannot but see great advantages in the manufacture and use as a blasting explosive of this offspring, as I cannot but regard it, of Dr. Sprengel's researches, and I should, therefore, class kinetite as *par excellence* "a safety explosive." If I can find evidence, or have it placed before me, to the contrary, it will be my duty, and I shall in fact hasten to renounce that position.

EXPERIMENTS.

After reading his paper, Mr. Watson Smith performed several experiments with a view to proving the safety attending both the manufacture and use of kinetite. (1.) He dissolved 5 of nitrocellulose in 100 of nitrobenzene, and heated the mixture even to ebullition over a flame (nitrobenzene boils at 205° C.). (2.) Some kinetite (made in November, 1885) was put on a strongly heated iron plate over the gas flame, nitrobenzene was rapidly volatilised, but no combustion ensued, until the flame was directly applied to the explosive, when the latter burned away steadily and somewhat slowly. (3.) Some kinetite was placed on an iron block, and was struck heavily with a hammer. Several explosions of those portions which actually came between the two iron surfaces occurred. (4.) Some kinetite was placed on a sheet of lead, which, again, was placed on the iron. Heavy blows were struck at this, with no result. On a second attempt a minute portion was exploded. The same experiment was repeated a third time, with no result. (5.) Some kinetite was laid on wood, and struck with a wooden mallet so as to produce a sliding or glancing blow. Repeated attempts to explode the kinetite in this way were made, but with no success. Some portions of the explosive adhered to the mallet, and were subsequently burnt off at the gas flame.

DISCUSSION.

The CHAIRMAN said Mr. Watson Smith had given a very interesting paper on this new substance. It was most remarkable to see how Dr. Sprengel's inventions had borne fruit. It seemed hardly possible now for an inventor to do more than develop one or another of Dr. Sprengel's ideas on the subject—in fact, all that remained for one to invent in respect of this class of explosives were variations in composition and in name. It seemed to him that the most interesting property of kinetite was its power of regular explosion. In this respect it appeared to be superior to dynamite, for if the latter were used in coal mining or in quarrying, its excessively destructive local action was always a great disadvantage. This new explosive, however, gave results more resembling those of gunpowder, and it would therefore appear to be a very valuable addition to our stock of blasting agents. Of course there might be reasons why the use of kinetite would be unadvisable; but, looking at the experiments they had seen performed, it did not appear to him to be a very dangerous body.

Dr. DUPRÉ observed that, if he, as the adviser of the Home Office in matters relating to explosives, might compare small things to great, he would suggest that the various gentlemen, whose reports had been read to the meeting, were "in a position of greater freedom and less responsibility," and everyone present would understand that he had to be cautious as to what he said. He had often, in teaching, compared these explosives to horses. Everyone was aware that a horse knew what sort of a rider was on him. He would do what a good rider wished him to do. But put a bad rider on him, and he would be nowhere. Similarly, it would seem that explosives knew when they were in the hands of a man who understood them. They then would do what was expected of them, but in the hands of an inexperienced individual, of course the individual would be nowhere. When kinetite was first introduced, Dr. Stahlschmidt had written him (the speaker) a letter urging him to recommend it as a perfectly safe and perfectly stable body. In fact, as in the case of every inventor of a safety explosive, the thing he had invented was absolutely inexplosive, except at the very moment when one had got it in the hole and wished to explode it. One might do what one liked with it—shoot at it, put it between two express trains, take it up a precipice and tumble it down—the explosive would never do harm unless one wished it. In his hands kinetite had proved to be neither stable nor otherwise safe. Kinetite was one of a well-known class of explosives, of which, as a rule, only the portion actually struck exploded. Sometimes one might strike them with a hammer without exploding them, at other times the slightest touch would set them off *en masse*. One might shoot at tons of dynamite when frozen without exploding it; in fact, at such a time it was scarcely to be exploded by a detonator. But the result would be very different in summer. There was an instance in which a poor man had lost his hand by merely taking a dynamite cartridge in his hand and striking it with a small hammer. It had become a proverbial saying in his laboratory, when the impossible happened, "It only explodes when iron strikes iron direct." And so the man with greater freedom and less responsibility thinks, "I have never succeeded in making it go off, and therefore it is safe." But it was well known that most serious accidents had happened through a comparatively slight touch of a hammer on such bodies. They ought not, theoretically, to have gone off, but, unfortunately, they had done so, and scattered people to atoms. There was one respect in which some of these explosives had an advantage; their constituents could be kept separate and mixed only at the moment when they were required. That was very admirable, in some cases, but it required much practical experience to decide when it was desirable. But, desirable or not, it could not be done in this country without an Act of Parliament. That was a point inventors should bear in mind. If they could get the power from Parliament, well and good; but at present no such power existed. To return to the question of the kinetite experiments. In the laboratory of the manufacturers two or three cartridges went off spontaneously—they ought not to have done so, but they did. Several hundredweights of the same suspicious composition were then in the magazine at the factory, and arrangements were made for their destruction. Accordingly, next day they went to remove them, but when they arrived they found that the kinetite had anticipated their action, and had burnt away. Fortunately it had not exploded. Sometimes these bodies did simply burn away; at others they exploded. But, supposing it were proved that kinetite would never explode under such circumstances, what would have happened if a ton of gun-cotton had been in the same magazine? Would the gun-cotton have remained unexploded? He imagined that even Mr. Watson Smith would not have liked to pass the night in the magazine containing these hundredweights of kinetite; and if he had done so, it was to be feared that the Section would not have had the pleasure of hearing him read the paper they had just listened to. Professor Lunge had said in his report that he had not found it possible to explode kinetite on wood. But he (the speaker) had found that in his hands it would go off on wood, on iron, on stone, on almost anything. Could it be that kinetite was unusually sensitive in his hands? And that was the great danger of all chlorate explosives. They were admirable; they were beautiful; but they had the very ugly knack of doing the wrong thing at the wrong time. If great caution were used, they were, as a rule, safe to keep; and kinetite itself was usually safe from explosion by fire. So one might often set fire to gun-cotton by the hundredweight or by the ton, and it would merely burn off; at other times it would explode. He had seen a hundredweight of dynamite burn off quite comfortably; at another time two or three pounds of it set on fire violently exploded—why, he did not know. These facts showed how careful those who were responsible for the lives of others should be. They could not be too cautious with respect to new explosives, whenever there was the shadow of a doubt about their safety. It was all very well for Mr. Watson Smith to show them the experiments he had made, but he (the speaker) might hint that he would have got an explosion more easily if he had struck his slanting blows *across* the grain of the wood instead of *with* the grain. Everyone who had the slightest experience of explosives knew that even gunpowder would occasionally go off if incautiously rammed down a hole. It ought not to, but it did. And how much more readily might such a thing happen with kinetite? Men of experience would know that gun-cotton might be struck at ordinary temperatures and it would not communicate a flame; but if it were struck at 100° F. the whole mass would probably go off. There was another considerable danger in these chlorate explosives which was at present little understood—viz., sensitiveness to atmospheric changes. If made of pure materials and carefully kept, they would last well. But if some of the same matter were exposed alternately to cold, damp, and to warm dry atmospheres, it would be found to be covered with crystals of chlorate of potassium, in which condition it was sometimes remarkably sensitive. With respect to the experiments mentioned by the author, he (the speaker) would be greatly obliged to any one who would show him any instruments by means of which the force of combined friction and concussion could be measured. He had never yet succeeded in measuring such force accurately. There was thus no exact measure of the sensitiveness of these explosives, but there was strong evidence that on being exposed alternately to moisture and warmth they became much more sensitive, and would occasionally go off with a very slight blow. He could say much more on the subject, but he was under considerable restriction as to freedom of speech. He would conclude by assuring the meeting that all these questions were considered by the authorities fairly and carefully, with the full knowledge that on their decision depended not only the introduction of improvements in an important branch of manufacture, but the lives of hundreds of their fellows.

Mr. W. Dalrymple-Borland said he had worked for a long time with explosives, and felt quite sure that chlorate mixtures were all more or less uncertain in action, both in manufacture and storage. There were one or two points upon which he would be glad of further information. First, as to the density of kinetite. Everyone knew that the density of an explosive was a matter of great importance. For instance, blasting gelatine had a great advantage over dynamite because of its greater density. For the same reason dynamite had the advantage of gun-cotton. He would therefore be glad to know the specific gravity of kinetite. Then as to the initial impulse required for explosion. From what had been said of its non-sensitiveness he should think it required a large impulse. That would be important. As to the experiments made to show the relative forces exerted, he could not but think that those cylinder tests, as carried out, were wholly unreliable and practically worthless. Under no circumstances could they give more than approximate results. There was one point in respect of this new body which had not been touched upon—viz., the gases of explosion. In these days of high explosives yielding gases practically innocuous—water, carbonic acid, etc.—any new explosive would stand a poor chance if its gases of explosion were noxious. Now, chlorates were well known to yield as a rule gases containing more or less chlorine; at any rate they were liable to do so. He would be glad to know whether this had been found to be the case with kinetite. He considered sulphide of antimony a most dangerous thing to use. If its employment had been abandoned, well and good, but he was not clear on that point. As to the experiment made by Mr. Smith to show the harmlessness of mixing gun-cotton with nitrobenzene, of course no new property had been imported to the gun-cotton thereby. It was observable that nitrous fumes were given off during the heating; but the gun-cotton being in very small quantity would not make itself felt to much extent. The anvil experiments shown were very interesting; but he did not think they showed kinetite to be safer than dynamite, or gun-cotton, or even gunpowder.

Mr. E. F. Herroun said that most of the remarks he had intended to make had been anticipated by the last speaker. It was a well-known fact that gun-cotton, as made for the preparation of potentite, was not sensitive to concussion. It might be remembered that in order to induce the Lancashire and Yorkshire Railway Co. to allow the carriage of potentite over their line, the makers ran some trucks over some potentite cartridges placed on the rails without damage. He had conducted many experiments of the kind they had seen, and had found that the explosion of the portion actually compressed was often not communicated to the loose portions. But he regarded such experiments as of little value, since the various accidents which had occurred with potentite and tonite (bodies which were comparatively safe) had demonstrated that the detonation of such bodies in a confined space might be very serious. He would suggest that the fact of the kinetite, or a large proportion of it, not being exploded by a blow indicated an imperfect action of its constituents due to their not being uniformly blended. Although a detonator had failed to cause complete explosion in some kinetite placed on an open boulder, still it was possible that a slight detonation, produced by the friction of a rammer in a bore-hole, might cause the explosion of the whole. He quite agreed with the last speaker in his remarks on the lead cylinder tests. No analysis of the products of combustion having been made, there was no evidence whether the kinetite had exerted all its energy or not.

Mr. John Spiller wished to inquire what was the nature of the detonator used for firing these cartridges, because the experiments of the late Edwin Brown had shown that much depended on this point. One could not but recognise the high value of Dr. Sprengel's experiments, which had initiated this and other contributions to the science of explosives. In the body placed before them that evening there would appear to be a very great excess of oxidising materials. If, as Mr. Smith had suggested, the antimony pentasulphide was to be kept out altogether, there would remain gun-cotton, chlorate of potash, and nitrobenzene—bodies all containing so much oxygen that one would expect it to be greatly in excess, or likely to become so when, by exposure, some of the nitrobenzene had vapourised. But his purpose was chiefly to inquire what sort of fuse had been used for detonating these cartridges.

Mr. E. Kennard Mitting wished to ask, in reference to the experiments in lead cylinders, whether any steps were taken to ensure that the earth was uniformly homogeneous round each cylinder. If not, that would account to some extent for the different results obtained by the firing of various cartridges.

The Chairman having called upon

Mr. Watson Smith to reply, he said he must at once bow to Dr. Dupré's much superior and wider knowledge of explosives. His own experience had extended over one year and a-half, and had all been laid before the meeting that night. Still, having heard what Dr. Dupré had to say on the subject, he could not help thinking that there was *at least* as much to be said for kinetite as for dynamite. They had heard much of the mysteries and misdeeds of dynamite and of the *possibility* of danger from kinetite. He could, of course, only judge by his own experience, and from that he judged kinetite to be stable and constant. If there were acid present in the nitrobenzene (sulphuric acid, for instance) he could understand that reaction would occur between it and the chlorate of potash; but that could easily be obviated by the addition of a small quantity of aniline.[*] Similarly, the presence of sulphide of antimony might possibly account for the heating which had developed in certain cases; but it was proposed to abandon the use of that constituent in England. This explosive was manufactured in Germany, and no mishaps had occurred; and he could not but regard most of the accidents and dangers they had heard of as being due to ignorance. A workman might have his hand blown off; but if he (the speaker) had to deal with kinetite, he took care not to put his hand in peril. He understood kinetite, but the workman in question evidently did not understand dynamite. He was not aware that Stahlschmidt invented kinetite, but had always understood that explosive was the invention of Petry & Fallenstein, of Düren. Mr. Smith had not determined the density of kinetite: but it might be roughly judged from the densities of its constituents—nitrobenzene, to begin with, being about 1·2. The ground in which the lead cylinder tests were made was of a clayey nature and was tolerably homogeneous. All the cylinders were embedded in the same kind of soil, close together, and the pressure on each would be about equal. He thought the bulges made in the cylinders showed the direction of the force exerted, and that an even bulge must be taken as indicating an equal development of force all round, while an extremely uneven sphere would show a greater development in the direction of the greatest bulge. As to the gases of explosion, he had not determined them; but he had never observed the slightest smell of chlorine in them. He would propose that the gun-cotton should be put into the nitrobenzene as soon as possible, and should never remain in stock; it should, moreover, be well tested for acid before being dissolved. When Dr. Lunge tested kinetite on wood, he had probably used direct blows only; but he (the speaker) had used glancing blows. It was quite true that both potentite and kinetite needed a large initial impulse to explode them; but then if one wanted safety one must be prepared to sacrifice something for it. One could not expect great sensitiveness, easy explosion, and safety at the same time. He was not a special advocate for potentite or tonite: those bodies were simply experimented on for the sake of comparison, the experiments being made in the Potentite Company's works. The detonators employed in the experiments described were Eggerstorff's sextuple detonators. He must confess himself ignorant of their composition; but they were very powerful, and on one occasion already referred to, one of them, although failing to detonate the kinetite in the open, had produced quite an explosion on its own account.

SOME NOTES ON GRINDING AND SEPARATING HARD SUBSTANCES.

BY T. W. B. MUMFORD.

Some four years since, the firm of manufacturers with whom I am connected, saw their way to do a largely increased trade in artificial fertilisers, but were limited to the quantity they could produce by the capacity of their machinery for grinding phosphatic materials. The opportunity I speak of came when there was a scarcity all round of the particular article required, and consequently profits were better than usual. This made us doubly anxious to secure the business; the only question was, How to do it?

Our margin of engine power was not very great, certainly not sufficient to drive millstones enough to produce what was required, and I therefore cast about for some other machine to help in the matter. I may say that every system which I investigated I considered unsuitable, either from the power required to work it, or from what, in my opinion, was equally important—the principle on which the various machines were constructed—whereby the probable wear and tear or gradually-diminishing efficiency of the apparatus would increase the cost of producing the article we wanted to make; so that what, under ordinary circumstances, was a very profitable margin between the cost of production and the selling price, would have been seriously diminished, if it did not disappear altogether.

I had long held the opinion that grinding phosphates by the aid of millstones was both primitive and expensive, but inasmuch as every manufacturer possessed machinery of that description, and it represented so many pounds sterling in his books as plant, it became a matter of some difficulty for me to get very much encouragement or information as to what had been done in other directions. There is of course this great advantage with millstones, they begin and finish the material ready for use, whereas other machines require some assistance in separating the fine from the coarser particles which they grind. It is not my intention this evening to inflict upon you

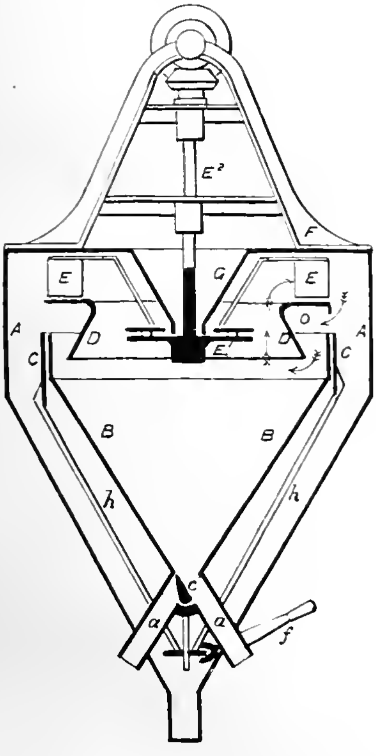
---

[*] This proposal was made by Dr. Sprengel in his paper read before the Chemical Society in 1873, and hence I claim nothing new for it.—W. S.

an account of my experiences in perfecting a grinding machine to help us out of our difficulties: suffice it to say that, having the good fortune to have as my chief engineer a thoroughly good all-round man, we were enabled to construct on our own principle a system of roller mills which not only met all our requirements for the time being, but which have been at work continuously ever since, and with the most satisfactory results.

With roller mills, as with every other machine outside millstones, the material after being crushed required to be graded. I found it was one thing to crush or grind the phosphate, but quite another matter to get an uniformly fine grade, which would fulfil the two essentials of profitable manufacture—viz., minimum insolubility of the mixed phosphates and sulphuric acid, with maximum condition of the finished article. We—and I daresay many other manufacturers are in the same fix—had not a large space at our disposal, and so were prohibited from erecting the ordinary exhaust apparatus with stive or dust chambers: we had therefore to fall back upon sieves, and here my troubles commenced. We tried every form—circular, hexagonal, and flat; iron gauze,

FIG 1



steel gauze, copper gauze, brass gauze, perforated plates, etc., etc., but all to no purpose; none proved satisfactory. Either a small hole would wear in the sieve, and, before the man in charge had discovered it, sufficient coarse material had got through to upset my calculations for insoluble phosphate; or, the material being slightly damp, the sieves became clogged, and we had to stop to brush them. Moreover I found that with woven wire the weaver was confined to a certain gauge of material, and that the finer the mesh required the thinner was it necessary for the wire to be; whilst the finer I found it necessary to grind the material the greater tendency was there for the sieves to become blocked, and the more necessity was there for them to be kept in a constant state of vibration, or to be brushed, and hence when most was required in this direction, the substance on which the operation had to be performed was far less capable of withstanding what it was necessary to do to keep the interstices free. The question was, What was to be done? Here we were with a splendid machine for grinding our materials, but it was impossible to shut our eyes to the fact that with the most perfect system of sieves we could devise or obtain, they would wear out, and moreover that we were at the mercy of our workpeople, who by inattention might, and did, bring about results which were the very opposite of what we desired.

My colleague, Mr. Moodie, after we had from time to time discussed this weak point in our armour, conceived the idea of the machine to which I wish to draw your attention, and of which I have a model on the table before me.

The diagram to which I will now refer will explain the principle on which the apparatus is constructed.

Section of Separator.

A, outer casing of sheet iron, circular in form, into which the fine dust is thrown, terminating in a spout at the bottom for delivering into bags, casks, on to creepers, etc., etc., as may be desired. B, inner casing into which the coarse particles fall, and can be delivered to the right or left through the branch pipes *a*, *a*, by moving the valve *c*. C, a movable band encircling the top of the case B, which acts as a damper for closing the opening between the cases A and B, and is worked by the lever *f*, and the rods *h*, *h*. D, hood against which the material is thrown. E, E, blades of fan connected by arms to the disc E^1, rotating on the fan spindle E^2. F, standard for carrying the spindle and driving gear, which may be bevel wheels or pulleys. G, feed cone into which the material is fed.

Mode of Operation.

The material to be treated is fed into the cone G, and, falling on to the rotating disc E^1, is thrown in a thin stream all round towards the fixed hood D. The current induced by the fan passes upwards and carries with it the fine particles, which are thrown into the outer case A; the current of air, separating itself from the fine particles by centrifugal force, returns through the opening O in the direction of the arrows, the same air being used over and over again. The coaser particles which are too heavy to be lifted by the current of air fall into the casing B, from whence they return by the branch pipes *a*, *a*, to the grinding machine to be further reduced.

The degree of fineness of the finished material can be regulated by the speed of the fan, also by the partial closing of the aperture O, by means of the damper C, which intercepts the current of air.

Different forms of hood D also alter the quality of the finished material.

I may add that I have found by using this separator in conjunction with millstones that I have been able to increase the quantity of finished material 60—70 per cent. continuously, and this without any additional wear and tear of the stones, or increase in the power taken to drive them, the reason being that the runner is raised as high as possible consistent with its still grinding the material between it and the bedstone. The material, coarse and fine together, after passing the stones is fed into the separator, the fine passing out by one spout, and being caught in bags, etc., in the usual way, whilst that which is not ground sufficiently fine is returned to the eye of the stones to be further reduced. I am working one 5ft. separator to every two pairs of millstones, and this arrangement leaves plenty of margin for materials which are much more easily ground than phosphates, and where the quantity of fine which two pairs of 4ft. 6in. stones will produce is in excess of what we are able to get from phosphate of lime.

Figs. 2 and 3 show this arrangement :—

A is the separator; B, B, millstones; C, elevator; *a*, *a*, spouts from millstones to elevator; *b*, spout from elevator to separator; *c*, *c*, return spouts for the coarse particles to millstones; *d*, spout for delivering finished material into bags, etc.

The machines have no wearing parts which come in contact with the material or which can get out of order: they are driven at a slow speed for machines of this sort. A finished material of any degree of fineness can be separated by it, and ones miller cannot by inattention vary the grade of the ground material. The separator also takes up very little room, and can be adapted to any system of crushing or grinding machinery.

In conclusion, permit me to say that by the aid of these machines we are able to keep our insoluble phosphate in our supers below 1 per cent., and at the same time the condition of the manufactured article is all that can be desired.

Local Sec. and Treasurer: W. P. Thompson, 6, Lord Street, Liverpool.

Meetings will be held at University College Laboratory, Brownlow Street, on Feb. 2, March 2, April 6 (Annual Meeting), and May 4, and the following papers have been promised:—

Prof. George Archbold, "On the Manufacture of Starch."
Mr. V. C. Driffield, "On Boiler Management."
Mr. C. Longuet Higgins, "On the Manufacture of Potassium Chlorate by means of Magnesia."
Mr. J. W. Macdonald, "On the Manufacture of Arrowroot in St. Vincent, West Indies; its Uses and Adulterants."

Notices of Papers and Communications for the Meetings to be sent to the Local Secretary.

A Meeting was held in the Chemical Theatre of the University College, Brownlow Street, on Wednesday evening, December 1, 1886.

PROFESSOR CAMPBELL BROWN PRESIDING.

DISCUSSION ON DR. HURTER'S PAPER ON PYROMETERS (THIS JOURNAL, 1886, 634).

MR. E. K. MUSPRATT said that the Siemens electrical pyrometer gave accurate results, at first, up to 800° C., but in a very short time it got out of order, and had to be discarded. He wished to know whether the instrument exhibited by Dr. Hurter could not be made less fragile. It was quite clear that up to 900° F. very excellent results were given, and the zero was not altered by constant use. If used in a works its fragility was very detrimental to its permanent use.

Dr. HAMBURGER said that he could only confirm Dr. Hurter's statement as to the inaccurate results obtained by the pyrometers which were usually employed in chemical works. The Steinle and Hartung graphite pyrometer gave at first very good results up to about 500° C., but if the instrument had once been quickly cooled, its indications were unreliable, and it must be adjusted very often. The Schäffer and Budenberg pyrometer also required frequent adjustment. The only trustworthy instrument was Fischer's calorimeter, but it must be carefully handled, and could not be left in the hands of workmen. He would also like to point out that in the September number of this Journal, p. 491, there was an article by Seger, who made extensive investigations on the fusibility of ceramic glazes. As a result he was able to arrange a scale of glazing mixtures, the fusibility of which, during regular intervals, served as an indication for the temperature. But, of course, this scale could only be employed for very high temperatures, such as prevailed in the pottery oven and so forth.

The Chairman (Dr. J. Campbell Brown) said he thought that the glass could be replaced by porcelain, but that platinum would hardly answer the purpose for many reasons. Platinum would be more apt to be influenced by outside pressure than either glass or porcelain.

Dr. Hurter said that with regard to the fragility of the instrument, he had certainly placed before them an instrument which looked exceedingly fragile. It was especially designed for taking the temperature of superheated steam in a part of their works, hence the reason for its peculiar shape. As to the amount of error which Mr. Carey mentioned, it was very considerable, amounting to 200° in 2000. With regard to making the pyrometer of different material, it was difficult to join a platinum or porcelain bulb to the mercurial gauge and air tight enough to stand the variations of temperature. Messrs. Heisch and Folkard proposed to make the bulb of platinum or porcelain, but how they were going to fix these bulbs he was at a loss to say. At a white heat, platinum and most metals become porous, so that gases transfuse through them, and he, therefore, was afraid that platinum would not answer the purpose. Porcelain might answer if a satisfactory joint could be made between the mercurial gauge and the porcelain bulb. Platinum, also, was too expensive. He was unable to give any information regarding Murrie's pyrometer, as he had not received any accurate description of it.

The Chairman, after stating that he had placed on the table a few specimens illustrating the manufacture of Saccharine, called upon Dr. Shack-Sommer to read his paper on the Manufacture of Sugar.

SUGAR REFINING.

BY DR. GUSTAF SCHACK-SOMMER.

Before attempting an account of the work of sugar refining, we must ascertain what the difficulties to be contended with are, and of what their nature consists. Now the object of the process is of course to remove the impurities from the raw sugar; and we find that these impurities are of two kinds—(*a*) mechanical, (*b*) chemical.

(*a*) The mechanical impurities consist of sand, remnants of the plants from which the raw sugar has been extracted, and other insoluble matters. These can be completely removed by careful filtration. This process may be accomplished either with *filter bags* or with *filter presses*. When filter bags are used the sugar is simply melted in hot water and passed through the bags by its own weight. This is necessarily a comparatively slow process. But a more expeditious method of filtration is that of driving the liquor through filter presses. In this case the sugar solution not containing solid impurities enough to enable it to saturate the pores of the filtering medium, and so to cause it to pass through slowly and become completely clarified in process, it becomes necessary to add something to it to improve the medium of filtration. For this purpose, it is customary to add such diverse substances as ground charcoal, sawdust, lignite, blood, albumen; or various chemicals, for example, lime, sucrate of lime, alum and its salts, and tannic acid. The first three substances named of course remain in the press without further aid from the refiner; the blood and albumen coagulate through the heat of the process, and are also, therefore, kept back; but the other substances require to be precipitated by the further addition of chemicals before going into the filter press.

(*b*) Secondly, we have to deal with the chemical impurities, and these are the most troublesome. They consist, first and foremost, of colouring matter; secondly, of those impurities which prevent crystallisation; and thirdly, of those which may destroy the crystallisable matter.

The colouring matter, of course, consists principally of vegetable substances which have not been separated from the sugar in the preparation of the raw. But, besides this, it is found that a considerable portion of the sugar itself has, owing to unskilful treatment, been turned into caramel, and this must also be removed before the colour can be improved. For this purpose, either animal charcoal or some artificial substance sharing its properties must be used. The only other method of decolorisation which need be mentioned is by using sulphurous acid over a filtering medium of gravel.

The impurities which prevent crystallisation are inverted sugar, foreign bodies of the albumen class, gums, and inorganic salts and bases: and their adverse action appears to be due to the fact that they intervene between the particles of sugar at the moment of crystallisation, and prevent its taking place. The correctness of this theory is proved by the fact that when these impurities are removed by the osmose process, crystallisation occurs freely. Raw cane sugar contains chiefly albumenic impurities, and the inorganic salts in it are not so difficult to deal with as those contained in raw sugar obtained from beet.

From experience, the refiner makes a rule-of-thumb calculation that the available hard sugar to be turned out from a given sample of raw cane is equal to the amount of the pure sugar contained therein, less three times the amount of salts and the amount of grape, or uncrystallisable sugar. From my own experiment I have found that the available in the raw sugar used during a whole year, and the hard sugar turned out during the same period, were practically the same. Pol. 84·25, avail. 72·15. Total cane sugar turned out in hard crystal, etc., but not taking into account what was boiled into tanks, 72 per cent. (cane in 77·5 per cent.).

The salts contained in raw beet are more injurious, and in consequence of this the refiner has to take his available hard sugar obtainable from beet to be equal to the amount of pure sugar it contains, minus five times the salt; but in this case the result can be only a purely arbitrary figure, because the sugar-liquor extracted from beet grown on soil near the sea, or in places where nitrate of soda is used as manure, are almost uncrystallisable. The salts of potash and the alkali hydrates appear to be most inimical to crystallisation, and these salts are also found to some extent in low-class cane—*e.g.*, Jaggery, 4·9 per cent.; Ilo Ilo, 5·8 per cent.; Egyptian, 6·30 per cent., 5·3 per cent., 0·8 per cent. And, moreover, the salts of potash are generally found to amount to two-fifths of the total salts present.

Mr. Duncan, of London, has for many years successfully used an alum process for getting rid of these salts. He first precipitates the potash in the form of alum, and then neutralises the residual liquor by the addition of lime. One part of potash requires, for conversion into alum, about 9·5 parts of sulphate of alumina, out of which 2·5 parts are required to convert the potash into a sulphate, and the remaining 7 combine with the sulphate of potash and form alum—

$$\left.\begin{matrix}4SO_2\\K_2\end{matrix}\right\}O_8+24aq.$$

$$\text{or, } K_2(SO_4)4+24aq.$$

	Beet Syrup.	After treatment, and before Char.	After Char.
Sugar	60·18	40·51	41·60
Ash	3·61	1·33	0·47
Water, etc.	36·21	58·13	57 93
	100·00	100·00	100·00

The alum is then separated from the sugar-liquor by the addition of lime-water until it only gives a dull red tinge to blue litmus paper, after which the liquor is pumped into the blow-up pans, and goes through the regular process of sugar refining. Another method of using chemicals in refining which is sometimes practised is as follows:—Five to ten per cent. of calcium sucrate is added to a pure sugar-liquor, and the mixture is treated with carbonic-acid gas until it is almost decomposed, when it becomes calcium hydrate, sucric acid, and carbonic acid chemically combined,* or more correctly, sucrate-hydrocarbonate of lime. This compound is mixed with the raw sugar-liquor which they desire to purify, and then the process of decomposing it with carbonic acid is completed. A very spongy precipitate is thus formed, which carries with it most of the colouring matter and other impurities. The inventors, Messrs. Boivin and Loiseau, of Paris, claim for their process that by its use not only is the yield of sugar increased and its quality improved, but that also less charcoal is required and less molasses turned out. With regard to this last point, however, it should be mentioned that the molasses obtained under this method is quite unfit for any purpose except distilling. A firm who use this process showed a sample of their molasses at a recent exhibition labelled "Syrup containing all the impurities." I think that statement is decidedly misleading, for most of the original impurities contained in the raw sugar were thrown down in the precipitate; and what makes their syrup unsaleable for consumption is impurities—that is, chemicals put in by themselves in the process. The process can only be advantageously employed for raw sugars containing a small percentage of inverted sugar, as, if there is much uncrystallisable present, it will combine with the lime, and becomes glucate of calcium, a substance which forms a sticky mass, and which, owing to its great solubility, cannot be got rid of throughout the whole process, and by its presence prevents a large proportion of the sugar from crystallising out. The most generally used medium of chemical purification, however, is animal charcoal. The substance is composed chiefly of carbon in a minutely-divided state, deposited on a groundwork of phosphate of calcium. For this reason it has a great power (probably entirely physical) of retaining most of the soluble substances as well as the colouring matters.

Raw Sugar from Java. Pol. 97·6.	Raw Liquor.	Liquor filt'r'd through Char.	Char Washings.
Crystallisable sugar	45·00	46·60	43·00
Uncrystallisable sugar	1·00	·30	1·80
Organic substances besides sugar	1·40	·00	1·35
Ash	·20	·10	·25
Moisture	52·40	53·00	53·60
	100·00	100·00	100·00

Raw Sugar from Manilla (so-called "Taal"). Pol. 74.	Raw Liquor.	Liquor filt'r'd through Char.	Char Washings.
Crystallisable sugar	35·40	41·20	36·00
Uncrystallisable sugar	9·40	6·40	7·80
Organic substances besides sugar	·00	·00	2·10
Ash	1·20	·40	·80
Moisture	51·00	52·00	53·30
	100·00	100·00	100·00

The analysis on preceding column, taken from the working of our sugar-house, shows the absorbent power of char, for the impurities contained in solution of sugar (gauge 24° B. at 63·5° F.).

I attribute the organic substances in the char washings of the taal to decomposed sugar.

The absorbent powers of char increase at high temperature. The finer the grain of the char, the more powerful its action. Certain inorganic salts—*e.g.*, carbonate of lime, and several substances of the albumen class—seem to be permanently retained by the char; but others, such as inorganic bases, combined with organic acids, and most of the inorganic salts, and gummy substances seem to be only temporarily retained, and are removable by the addition of thinner liquors, or by washing with hot water.

If the refiner could use just the amount of char necessary to absorb the colouring matter and the salts which he desires to have removed, and could then let the sugar-liquor drain off, he would reap the full advantage from the char; but as he cannot afford to waste the sugar adhering to the particles of char, he has to wash it out with hot water, and then these thin liquors contain nearly all the impurities which the raw sugar originally contained.

The absorbent power of char ceases sooner for salts and other impurities than for colouring matters. In connection with this we may note that a thin scale is often formed in the pans in which these thin liquors are evaporated, and it has been found on analysis to contain—

Lime	25·87
Magnesia	0·40
Peroxide of Iron	0·28
Alumina	0·88
Oxide of Copper	3·50
Oxide of Lead	0·17
Potash	9·70
Soda	0·42
Sulphuric Acid	41·00
Phosphoric Acid	0·19
Carbonic Acid	4·30
Insoluble Siliceous Matters	3·75
Combined Water	7·84
Organic Matter, Loss, etc.	1·70
	100·00

Several substitutes for char—for instance, a carbonised mixture of 100 parts of pipe-clay, 20 of tar, and 500 parts of coal-dust—have been brought forward, which may, in their fresh state, have the same effect as charcoal, but they lose their power more quickly on reburning. But why English manufactured charcoal is so much better than foreign make I have not been able to find out. Here is a field for research for chemists, and I hope someone will read us a paper on char soon, that we may ventilate this very interesting subject.

Before the char is used, it is necessary to wash carefully all the salts out of it. The first water con-

---

* See Lock, Wigner, and Harland's excellent treatise on "Sugar Growing and Refining."

tained 464·4 grains of salts per gallon. After eight hours' washing with boiling water, the wash-water still contained 99·3 grains of salts per gallon ; after eleven hours, 39·3 grains of salts per gallon : after fourteen hours, 23·8 grains of salts per gallon ; after seventeen hours, 9·20 grains of salts per gallon ; and after twenty hours, 2·8 grains of salts per gallon.

The impurities which destroy the crystallisable sugar are principally acids. The organic acids, although themselves not very powerful, may liberate the acid in the salts, and then play havoc with the crystallisable sugar.

The lime or lime salts contained in the charcoal or the substances put into the pan, when the sugar is melted, are the only possible remedies for this evil. The sugar refiner, during his whole manipulation of the material, is constantly adding to the impurities it contains. To begin with, he dissolves the sugar in water, although he knows that in time a sugar solution will be decomposed into ulmic acid and water. A Java sugar having got wet on the journey altered very much, as the analysis shows :—

	Moisture.	Other Organic Substances.	Ash.	Invert Sugar.	Pol.	Avail.
Sound Java Sugar......	0·2	0·1	0·4	0·8	98·5	96·5
Washed Java	5·2	2·7	0·2	8·1	83·8	75·1

Then he heats the solution, knowing full well that heat is favourable to the inversion of sugar. In fact, Souteiron has shown, experimentally, that a solution of pure crystals of pol. 71·0 after two hours' heating polarised only 68, after four hours 58, after eight hours only 38, and so on. This shows how necessary it is for the refiner to guard against high temperature during his processes. He should never get higher than 60—65° Celsius, say 140—150° F. The same chemist proved, by repeating the experiment with a solution covered with oil and attaining the same result, that this waste was not due to the action of the air.

This inversion is not due to the sudden application of heat, but is brought about by the action of long-continued raised temperature, and, therefore, the more quickly he can accomplish the process of refining, the less liability to loss of crystallisable sugar is incurred. To give an example from practice, it has been found that in working raw of a polarisation of 84·25 for a considerable period there was a loss of cane amounting to 12·25 per cent. on the raw melted, which was equivalent to 14·60 per cent. on the crystallisable melted. Of this loss half would go in molasses turned out, but the other half of the lost crystallisable must be attributed to inversion. Not only must heat and water be guarded against, if we wish to keep down this tendency to inversion, but sunlight must also be avoided, as it has a similar power of inverting cane sugar, as the following experiment of Maumené shows :—

He took two similar glass tubes filled with pure cane solution, and kept them from the 12th of May to the 20th of October—one he exposed, the other was in complete darkness—both were kept at the same temperature. At the end of this period he found that half of the first solution had become inverted, whereas the other remained in its original condition.

It may be well here to mention another cause of inversion, which, however, does not come under the control of the British refiner. It is the practice of some planters to cut the canes more quickly than their mills are able to crush them, and for this reason the canes often have to lie several days, after they have been cut, before they reach the mills. During this period fermentation sets in, and in the result the raw sugar derived from them contains an unduly large proportion of inverted sugar.

From the prominence we have given inverted sugar, it will be seen this is one of the worst difficulties with which the sugar refiner must contend, and it will, therefore, be well to give some account of it, though it is a substance of which comparatively little is known. It cannot be classified by its crystallisation, nor by its constant qualities, for it is a mixture of restless particles of saccharine matter, which are always changing the position of their molecules. Inverted sugar can remain without crystallising for months, until suddenly, without apparent cause, it deposits crystals which turn the polarised light to the right, and are, therefore, called Dextrose. Uncrystallisable, on the contrary, turns the polarised light to the left, and is known as Levulose. These two are present in irregular proportions in inverted sugar, and the process of inversion is believed to take place by one molecule of cane sugar combining with two molecules of water, and forming a mixture of dextrose and levulose :—

$$C_{12}H_{22}O_{11} + H_2O = \underset{\text{Dextrose.}}{C_6H_{12}O_6} + \underset{\text{Levulose.}}{C_6H_{12}O_6}$$

Dextrose crystallises in the form of twin crystals of the triclinic system. The presence of inverted sugar always depreciates the value of the raw, but I also have strong suspicion that the cloudiness of golden syrup (refined molasses), which is the great trouble of some refiners, since it renders their residual product unsaleable, is due to the dextrose crystallising out after a more or less considerable time has elapsed since the manufacture has been completed.

Dextrose, indeed, is troublesome, not only in its simple form, but also in its combinations with organic and inorganic bases. Inverted sugar and lime in combination form a very easily decomposed salt, which, if exposed to the sunlight for a few minutes, turns from white to a dark brown, approaching black, and in that state is proof against further decomposition by carbonic acid.

These properties of inverted sugar render it impossible for the refiner of cane sugar to profit by the new methods of refining more universally practised on the Continent for extracting the crystallisable sugar from molasses, by the means of compounds of lime strontianite and baryta. I need only refer to such processes as those of Manoury and Scheibler, which, though excellent for beet, are impracticable with cane sugar. Though I may mention here that the French Government has prohibited manufacturers at Aubervilliers and Wallers from using the last ingredient on account of symptoms of poisoning, which showed themselves not only amongst the workmen employed in the manufactories, but also amongst the animals and vegetables for miles round the works. A. M. V. Gayon has proposed to destroy the inverted sugar by means of a fungus called Mucor, having made the discovery that fermentation with that fungus will only attack the inverted sugar in molasses, and leaves the cane sugar intact. In this process the solution must be first boiled so as to prevent all other fermentation, then it is impregnated with the mucor circinelloides, and whilst the fermentation is proceeding, any air which is admitted has to be either filtered through cotton wool or passed through red-hot pipes, so as to prevent the possibility of the approach of any other germs. The liquid itself must be maintained at a temperature of 35—40° C. during the process, but afterwards may be gradually lowered to 20° C. to avoid evaporation of the alcohol. After the fermentation is over the alcohol is distilled off, and the sugar is secured by the usual methods of crystallisation.

It has often been remarked that beet-root sugar has less sweetening power than cane sugar. This could be accounted for by the fact that there are substances —*e.g.*, Peligot's discovery, Saccharin—which have the power of turning the polarised light more than cane sugar, and have many of its properties as well, but have no taste whatever. Peligot's Saccharin—which should not be confused with Fahlberg's Saccharine, to which I will refer later on—is produced by the action of hydrate of calcium on inverted sugar, a product which is very apt to be generated by the method in which beet-root sugar is made on the Continent.

I am also unable to give any definite reason why fruit preserved with beet-root sugar, or refined sugar made from beet root, will not keep. The only explanation to be offered for this is that the salts, which are never totally eradicated from beet-root sugar, favour fermentation.

Now it will be seen, from all we have said, that the sugar refiner has to overcome many difficulties, and to overcome them all at the same time. Thus, if he does not use sufficient heat in his process, he prolongs his operation and favours fermentation. If, on the other hand, he uses too much heat, he caramelises the saccharine matters. Again, if he does not get rid of the foreign bodies and the acids, the sugar will not crystallise, yet he injures the raw material in the process of destroying them.

It now becomes necessary for the sugar refiner to convert his pure sugar liquor into a solid substance in a saleable form.

This is done in modern refineries by first boiling the liquor in vacuum pans, and then separating the formed sugar crystals from the syrup, by means of centrifugal hydro-extractors. When viewing the present rapid and inexpensive methods of accomplishing these ends, it is almost impossible to conceive that only a very few years ago sugar refiners were content to separate their hard sugar from the syrup by the slow process of drainage, which not only caused great loss by the time which was wasted and the room which was required to accommodate the moulds for several days' melt, but also caused the sugar to become very hard and insoluble, and this evil was intensified by the practice of "sucking" air through the sugar, so as to dry it after the drainage had run through. This comparative insolubility is another reason why Titlers are now so little used, as, though old habit was with difficulty broken, customers have at length begun to find that ready-made cubes not only are a saving of labour to the purchaser by relieving him from the trouble of chopping his sugar, before using it, but they may consist of sugar quite as pure as the old loaf sugar, and are much more soluble than it ever could be.

It is strange that though all these objections to moulds were well known at the time, refiners persisted in using the old process long after the invention of the centrifugal hydro-extractor; and I well remember, when I was a student, that this fact suggested to my professor a long dissertation on the struggle by which real economy has to overcome old fashions. Similar fashions still hold their sway in our trade, for in many parts of Lancashire and Yorkshire there is a great demand for immense crystals which owe their size to the great temperature at which they are boiled, though it is well known that this high temperature renders them very insoluble. Not only can fancy prices be obtained for these large crystals of pure sugar, but, especially in the South of England, grocery Demeraras, which are merely a highly crystallised raw cane sugar, are much sought after, as there is a very unfounded belief that they contain more sweetening properties than white crystals of pure sugar.

Grocers frequently complain that refiners sell them water instead of sugar. Now it is a fact that pure crystal sugars contain less than 0·5 per cent. of moisture, and it is to the presence of this modicum of water that the sparkle, which is so much sought after, is due. And the very people who cry out so loudly about "wet" crystals are the first to reject absolutely dry sugar on account of its dulness and want of sparkle.

A paper on sugar refining at the present time would be very incomplete without a reference to the alleged discovery of "Professor" Friend; I refer of course to electric sugar refining. When it is borne in mind how many different kinds of foreign bodies are wont to be present in the raw material, and how easily the pure sugar is injured and even destroyed in the process of eradicating them, it will be understood what an immense stride that gentleman claims to have made when he says that he can almost instantly refine sugar at a merely nominal cost and with a merely nominal loss in the process.

He claims first, to quote the words of his own pamphlet, that the process will refine any grade of sugar, and that raw sugars of the lowest grades are as easily, cheaply, and effectually refined as raw sugars of the highest grades. Secondly, that the whole saccharine matters in the raw sugar, including the invert, within the merest trifle is returned in refined sugars of the highest grades similar to those exhibited, and he claims that the invention is an entirely new process of refining sugars. It is dry throughout, dispensing altogether with boiling and the use of bone-black; no syrup whatever is produced, but the whole product is hard sugar of nearly, if not quite, absolute pure sugar—viz., 100 per cent. of pure sugar, as per analysis. A principal feature of the process is the use of electricity, concerning which the inventor claims that he has discovered a new method of producing it at a nominal cost. Knowing definitely nothing more than this about Professor Friend's process, one can of course only speculate as to how this problem is to be worked out, bearing in mind all the difficulties with which the sugar refiner is surrounded. To begin with, it is stated that the process is an entirely dry one, and I have the Professor's own authority for the statement that at all events he did not use "more than perhaps a bucket full of water" in the whole course of his great demonstration, when on the 14th July, 1885, he produced 40 barrels filled with refined sugar of 12 different sizes, ranging from cubes of nearly an inch cube down to powder. Now, as I am not aware that one can bring about crystallisation of sugar without first passing the substance through the stage of solution in some liquid, I can only suppose that when the Professor speaks of his process as a dry process, he means us to understand either that he does not dissolve his sugar in water, but uses some other solvent for the purpose, or that he fuses it by heat. The first alternative is the most likely one, as it would be almost impossible to keep sugar in a sufficiently high temperature to fuse it, without at the same time turning it to caramel, for even at 160° C., the fusing point of sugar, it decomposes very rapidly. The peculiar agglomeration of crystals which form the sample of refined which he has produced, even favour the first theory. But in spite of this I should personally be inclined to believe that this solvent had been applied after the refining process had been completed, for all the individual crystals of electric sugar belonged to the monocline form of crystallisation, that form which sugar invariably takes.

For the second place I must refer to the statement regarding the application of electricity to the purification of sugar. Now up to this time there has been a general agreement amongst scientific men to the effect that sugar is a poor conductor of electricity, and that it is totally unaffected by the action of the electric fluid. But Professor Friend is not the only person who claims the invention of a process of sugar refining by electricity, for last year, in *Dingler's Journal*, cclvii. p. 298, we find it stated that some people in Lyons claim to have obtained sugar by the following method :—They boiled 100kilos. of potatoes in 5 cubic metres of water containing 5kilos. of sulphuric acid and a trace of nitric acid. They passed through this an electric current of 11 ampères. The electrodes were of antimonial lead, and the flow of the current was continually changed. After two hours it was tested and all the starch had disappeared, and then first the acid and then the saccharine matter was precipitated with lime, and from the precipitate the latter freed by carbonic acid when it had been evaporated and crystallised. The result of this experiment was analysed and found to contain

Water	6·95
Ash	3·67
Grape	1·00
Cane	88·38
	100·00

I could never verify this startling announcement, and Professor Scheibler, of Berlin, whom I consulted about it, told me it was a misapprehension, and Professor Landolt, at the general meeting of the Rubenzucker Industrie, in July, 1885, made a statement to the effect that no progess had been made up to that date in making use of electricity in the process of sugar refining. I had a letter a few days ago from Mr. Gill, of London, who investigated the invention personally and found there was no truth in it whatever.

There is one method in which it may be possible to use electricity in sugar refining, but I do not think it has ever been attempted in practice. That is, to create ozone by passing electricity through oxygen and then decolorising the sugar with the product. Patents have been taken out by several persons for the use of electricity in sugar refining, but they all propose to purify the liquor from the salts by decomposing them into their constituent parts ; and under the working of each patent there is an increase of uncrystallisable in the process. I need only mention the excellent experiments made in the sugar house of MM. Dudok, Devitt & Co., at Amsterdam, which were quite unsatisfactory in their results. As regards the patents of Mr. Louis Henri Despeissis, of Paris, taken out 30th August, 1883, and of Joseph Goiz, of Berlin, taken out 27th November, 1883, they have not proved of any practical advantage, and neither have been adopted.

I have now given all the information which can throw any light on the probability of the electric process being practicable, and I think you will agree that the practical difficulties of sugar refining prevent any likelihood of electricity being advantageously employed in the process. I do not for a moment pretend that it is an impossibility to make cane sugar from invert, in fact I believe that some day it will be rendered practicable to do so ; but when that is done I think the inventor will be able to use other and cheaper sources for his raw material than either the sugar cane or the beet-root, and here I do not mean crystals of invert sugar, such as Mr. Behr, of New York, has produced, but I mean crystals of cane sugar to be produced from the invert sugar.

Before I close this paper I would like to mention that saccharine, which is one of the products of coal tar treated in the manner described on a former occasion in this Society, would seem to a chemical mind to be poisonous, or at least prejudicial to health, but experiments made by medical men, first on animals and afterwards on human beings, have proved that it shows no evil effects. In fact it passes through the body without decomposition, as a cherry-stone would do. The whole amount administered to a person can be afterwards recovered from his secretions. Now, of course, to sufferers from diabetes mellitus and gouty persons saccharine may be a boon, as it will allow them to enjoy the sweetness of sugar and similar carbohydrates without their, to them, injurious effects. But sugar planters and refiners need not be afraid of this substance, for it has only the power of conveying the sweet taste of sugar to the palate. It is absolutely without the nutritious properties of sugar.

Experiments on dogs have shown that a diet of sugar, combined with a modicum of fat in order to ensure the complete assimilation of the sugar, will be sufficient to keep up the vital forces for a long period, that in fact sugar contains all the nutritious elements necessary for sustaining life.

There are many substances which, on entering the stomach, are converted by the process of digestion, first into sugar and afterwards into fat, and it is found that children and persons with weak digestion are much benefited by a diet containing a quantity of sugar, as the preliminary process of digestion is avoided, and the sugar becomes fat almost immediately upon its reception into the body.

Moreover, there is another digestive property of sugar, which is also common to salt. This is the power of exciting the salivary glands which makes it possible for many other substances, of themselves indigestible, to be eaten without danger, because it causes them to be thoroughly impregnated with saliva before they are swallowed, and thus easy of digestion, a property which is not possessed by the coal-tar sugar.

A company with a capital of £100,000 is now established at Madgeburg, to manufacture this substance on a large scale, but I cannot believe that it will ever find its way into the grocer's shop ; it is much more probable that it will remain on the druggist's shelves, where, doubtless, it will be found very useful for medicinal purposes.

In spite of my conviction that neither of these much-talked-of competitors are dangerous to the sugar refiner, I think it will be seen from the few remarks that I have given you, that the sugar refiner has sufficient real difficulties to contend with in his business to render it very necessary for him to bring all the resources of his experience and all the knowledge of chemistry he can command to his aid, if he attempts to compete with the bounty-fed productions of the Continent and the United States.

DISCUSSION.

The Chairman said that they had had a most interesting and instructive paper from Mr. Shack-Sommer, and that there was a great deal of room for remarks and discussion. He believed there was present a representative of the Electric Sugar Co., and had pleasure in calling upon

Mr. Robertson, who said the reader of the paper had mentioned that he did not understand what Professor Friend claimed as his process. This being so, his criticisms of what he did not (admittedly) understand could not be of great value. He might have been mistaken, as owing to the reverberation in the room he had not quite caught every word of the reader.

He had been requested to attend the meeting, as being perhaps the heaviest English investor in the Electric Sugar Company. He had been to New York to see and learn all he could about what was claimed for this new invention. He attended what was called a demonstration at Professor Friend's house, at which time nine barrels of raw sugar were given him to refine, and after two hours and a half he was shown what was said to be the result—eight different sizes of refined sugar, some of which was now shown. Professor Friend would allow no one to see how he refined the sugar, nor his machinery either, and was keeping the process secret. He was fully convinced that Professor Friend had done, and could do, all that he claimed. He had invested moderately before going out to New York, but after attending the demonstration alluded to, and becoming acquainted with Professor Friend and his family, he had more than doubled his investment, and had induced other members of his family to do likewise; but this did not prove anything beyond his own faith in the invention. He had never heard a single expert in sugar deny that the product was a new one; the process being a new one unknown to anyone but the inventor. He could not say how it was done, but thought it only reasonable to give Professor Friend credit for what he claimed, seeing that no one had yet produced the same character of refined sugar as that shown. He was so confident of the *bonâ fides* of the inventor and all he claimed, that if he could afford it he would double his holdings in the company. He had pleasure in placing before the members several specimens of sugar refined by Professor Friend.

Mr. E. Carey would like to ask Dr. Shack-Sommer one question. He understood him to say, as a kind of general statement, that crystallisation could only be induced from a state of either solution or fusion. He might have misunderstood the remark, but would observe that there were many instances in nature of crystallisation without solution or fusion, as, for example, the crystallisation of wrought iron when exposed to continued vibration. The iron gradually became crystalline and brittle instead of being fibrous and tough.

Mr. Muspratt said he would be glad if Dr. Shack-Sommer could give them some further information as to the way in which the poisoning referred to in his paper had taken place. As he understood that when baryta salts were used in the way described in the paper, an insoluble precipitate was formed, it seemed difficult to understand how the use of these salts could affect the surrounding people in any way. The poisoning must have been serious to cause the Government to interfere in the matter.

Dr. Schack-Sommer said that his information was derived from Scheibler's *Zeitschrift für Rübenzucker Industrie*, vol. xvii. No. 13, p. 167, where it is stated that the works of Mr. Lebandy, at Aubervilliers and Wallers, had been closed by order of the Government on account of sickness amongst the workmen, manifesting itself, in the first instance, by the falling off of their hair, as well as the destruction of all animal and vegetable life for a considerable distance round, the poisoning of the neighbouring streams, and the pollution of the atmosphere, which was noticeable for miles round. He had no particulars as to how it took place.

Mr. Henry Brunner said that he thought the reason why beet sugar was not as sweet as cane sugar was due in some measure to the presence of the salts contained in the syrups or molasses adhering to the sugar.

Mr. J. W. Macdonald said he thought that the poisoning caused by the use of baryta, was due to the small particles flying about, owing to the handling and slacking of the caustic baryta. This could be considerably obviated by care in the construction of the works, keeping the baryta department by itself, and having it closed in as much as possible. This would only affect the workmen in the baryta department, and would be no worse than in other industries where compounds of baryta, lead, arsenic, and such like substances were manufactured or used. The baryta could not affect the consumers of the sugar, for it was completely precipitated by carbonic acid gas, and the carbonate of baryta filtered off. Even should a trace of baryta compounds remain in the molasses, it would not appear in loaf and crystal sugars, which were washed free of molasses. He quite agreed with Dr. Shack-Sommer's remarks on the so-called electric sugar process of Prof. Friend. He thought the professor's claims preposterous, and the public should know what those in the sugar industry thought of the process. Prof. Friend claimed to have discovered a means of separating the sugar from the innumerable organic and inorganic impurities contained in raw sugars. He also claimed to have converted the glucose into crystallisable sugar, and to separate it along with the sugar. Any of these results would be most remarkable, if obtained in a wet process; but the process was also said to be a *dry* one. Now, sand and other insoluble matter could not be separated from sugar crystals by a dry process. You must have solution and filtration. Prof. Friend did not tell them what became of the potash salts and other soluble impurities which at present formed molasses. All that he showed was sugar and such like substances as sand, fibre, and the various substances at present removed in the refineries by *filtration*. Very similar sugar to the "electric" sugar could be made by gently crushing loaf sugar, and separating it into various sizes by a set of different sieves. If the process were so very valuable, the Americans would very soon subscribe the necessary capital. As to the sweetening property of cane sugar, he thought the flavour contained in raw cane sugars helped to make the taste of those sugars so pleasant. He believed that pure sugar made from cane or beet had the same sweetness, and that if each were introduced into the mouth under the same conditions, it would be found that the effect on the palate was the same. By *pure* sugar he meant loaf sugar, cube sugar, crystallised sugar, and granulated sugar, all of which contain practically 100 per cent. of actual sugar. If *yellow sugars*, however, or "*pieces*," containing syrup, were being tasted, those made from beet would not taste as sweet as those made from cane, because of the salts contained in the syrup. The salts in beet syrup were more abundant and also more nauseous, weight for weight, and, therefore, neutralised a greater quantity of the actual sugar (or sweetness) present in the sample. He had made some *pure* crystallised sugar (testing 100 per cent.) both from raw cane and raw beet sugar. These crystals were made under exactly the same conditions. Equal weights of each were then dissolved in equal volumes of water. These equal solutions were then tasted by different persons, care being taken to introduce into the mouth equal quantities of these solutions. The general opinion was that no difference in sweetness could be distinguished. Equal quantities of the original crystals were also tried in the mouth; they also produced apparently the same sweetness.

Mr. W. P. Thompson said that although he was not a believer in the electric sugar, he did not think it was out of the bounds of possibility that Prof. Friend might have discovered some method of subliming sugar in combination with some solvent or other chemical, so as to form a sublimable composition, then to precipitate the sugar from that compound by means of electricity, or other means, so as to form crystals.

Dr. Hamburger stated that Dr. Sommer had not mentioned a new process for the purification of sugar solutions, which had been patented by two Austrians (Englert and Becker). The details of the process were not present to his mind, but he knew that the purification was brought about by the action of the alumina compound of Schützenberger's hydromonothionic acid. On boiling, the latter was decomposed into alumina and hydromonothionic acid, which destroyed the colouring matter present. He remembered having read that the process had been introduced into several Austrian works, where it was worked with perfect success.

Mr. Norman Tate, referring to the preservative properties of sugar, thought that sufficient attention had not been given to the inorganic salts in the two kinds of sugar. He could not help thinking that the difference in the amount of sulphates, phosphates, etc., would frequently have some very considerable influence in the use of one sugar as compared with the other, as a preservative agent. He also thought the reference to the presence of mucor made by Mr. Schack-Sommer, was worthy the close attention of sugar manufacturers. Further biological investigations on the effects of the presence of mucor and other organisms would, he thought, result in great advantage to sugar refiners.

Dr. Hamburger asked whether the potassium salts could be separated from molasses, or whether the molasses would be fermented first?

Dr. Schack-Sommer replied that the alum process had been used by Mr. Newlands, of Messrs. Duncan's, to get the potash salts, and the chemicals were obtained as by-products.

Dr. Hamburger asked whether those salts were precipitated?

Dr. Schack-Sommer replied that they were.

The Chairman, before calling upon Dr. Shack-Sommer to reply, said with regard to electric sugar, they were very glad to see present so able a representative of the inventor's interest, because they had had put before them the whole and sole evidence that had been adduced in favour of the inventor's claim, which was that a gentleman took a number of bags of raw sugar from one room into another, and after a certain time had brought certain bags, bottles or specimens of refined sugar from that second room, there being no evident connection between the one and the other. They were given to understand that the assertion was made by him that the refined sugar came from the unrefined; but there was not the slightest particle of proof to support the statement. In the absence of that evidence manufacturers entirely declined to believe in it. There was a very proper tendency to disbelieve everything that is absolutely secret—spirit rapping, for instance; and until some indication was given of the connection between the raw and the refined product of that process, they could not expect reasonable people to give it credence. He did not *say* that the process was not true, but there was no piece of evidence produced that would cause people to invest money in it; and he could only express a hope that the gentlemen who had so generously and boldly risked their money, might get it back again some time. With regard to the use of ozone, he had seen a gentleman interested in that subject perform a large experiment, the only result of which was that the sugar was a little darkened rather than lightened.

Dr. Schack-Sommer said, in reply, that he would first inform Mr. Robertson that he had not come there that evening to attack the Electric Sugar Refining Co., or any other company. His purpose was only to investigate, from a scientific point of view, the probabilities of the alleged invention of Prof. Friend, and he believed he had proved to all present, save Mr. Robertson, that according to all scientific rules yet known, this "wonderful" discovery was entirely inexplicable. As regarded Mr. Thompson's suggestion that probably the process was performed by sublimation, the plain answer was that sugar and its compounds do not sublime: but he quite agreed with Mr. Thompson that crystallisation could take place from vapours, considering that in the gaseous state the atoms of a substance were merely the atoms of it in the liquid state, considerably expanded. As to the poisoning in the neighbourhood of baryta works, he did not think it impossible, as from his own experience in the manufacture of white lead he found by chemical reaction that traces of the lead salt were perceptible at great distances. If acetate of lead could do this, he did not see why baryta salts should not go further than was imagined. As to beet sugar, he knew a wholesale grocer who by smell alone was invariably able to tell if a sample of pure white sugar polarising 100, submitted to him, had been derived from beet or cane. The only explanation he could afford Mr. Tate as to the salts was the one he had already given.

Meeting held Wednesday, January 5, 1887.

DR. HURTER IN THE CHAIR.

The Chairman said that before calling on the Secretary to read the first paper, he would ask if any member had a communication to make?

Mr. J. W. Macdonald said that as the question of the different sweetness of cane and beet sugars was brought up at the last meeting, he had brought samples of refined sugars made exactly in the same way from raw beet and cane sugars. He would place these on the table for the members to examine. It was a pity that the report of the last meeting of this Section was not yet published, so that they could have read the remarks with reference to the sweetness of beet and cane sugar, before they came to this meeting. He had also brought samples of *raw* cane and beet sugars, which contained exactly the same saccharine strength, so that the members could be able to judge of the sugars before and after refining. They would see that the raw beet was very nauseous, and that the raw cane was sweet and pleasant, but that there was no difference between the pure refined articles from each. Many persons said that beet sugar was not as sweet as cane, but he would qualify that by saying "raw" beet sugar.

Dr. Hurter said that perhaps some of the members would endeavour to find out by taste which sample was from beet and which from cane sugar.

After due examination most of the members—in the proportion of about 4 to 1—thought that the sample made from cane sugar had been made from beet.

NOTE ON MAHWA FLOWERS, AS A SOURCE OF SUGAR.

BY H. S. ELWORTHY, F.C.S.

Some months ago an article appeared in one of the English morning papers in regard to the manufacture of sugar from the flowers of the Mahwa tree. The article in question gave a very sensational account of the capabilities of the tree, and its sugar-producing powers, placing the amount of sugar at 50 per cent. on the dried flowers. Figures were also given to show the large amount yielded by each tree, and the number of trees which could be grown on an acre of ground. It was made out quite to the satisfaction of the writer that the sugar cane had met with a far more formidable rival than the beet.

Thinking it worth while to investigate the matter, and having facilities for obtaining the flowers in any desired quantity, I tested 4 samples from as many different places, with the following result :—

	Sucrose.	Invert Sugar.	Dextro Glucose.	Total Sugar.
No. 1.—From Hyderabad . ..	17·1	40·0	—	57·1
,, 2.— ,, Jubulpore..	4·6	41·4	—	46·0
,, 3.— ,, Guzrat	9·6	45·3	—	54·9
,, 4.— ,, Mirzapore	6·7	—	43·6	50·3

The above analyses will show that the Mahwa is totally unfitted for the manufacture of crystallisable sugar, although possibly available as a source of brewer's sugar. The spirit made by a direct fermentation of the flowers contains an exceptionally large proportion of fusel oil, and has a very strong unpleasant flavour. It would, therefore, require very careful purification. This tree, *Bassia Latifolia* (Roxb.) is indigenous to the forests of Central India, and is largely cultivated in many other parts of the country. It forms a valuable source of food to the poorer classes in the district where it abounds, and considerable quantities of native spirit are made from it. It is not generally fermented alone, but is mixed with about one-third of molasses. As previously stated, it contains a large quantity of fusel oil, one sample examined by me having no less than 3 per cent. of this dangerous ingredient. The price of the dried flowers ranges from about 2 rupees 8 annas to 3 rupees per maund of 82⅖lbs.

Some time ago considerable quantities of the flowers were shipped to France, but for what purpose I am unable to say, and I believe the shipments have been stopped.

There was also a kind of brandy made from the flowers by a European in the Punjab, some years ago, but this has also been stopped.

DISCUSSION.

Mr. A. Watt said it seemed to him, from the analyses given, that the flowers were totally unsuited for the manufacture of sugar, owing to the small proportion of sucrose contained in them. He thought they might suit "Professor Friend," as the glucose was just as useful for his purpose as the sucrose.

The Chairman, in reply to a question of Mr. N. Tate, said he thought that the percentages given in the paper were from the dry flowers. The sugar trade appeared to him to be like the alkali trade, a new ghost turning up every day to frighten manufacturers. He thought the paper would do good in dispelling wrong impressions.

ON VALENTA'S TEST FOR OILS.

BY GEORGE H. HURST, F.C.S.

In *Dingl. Polyt. J.* **252**, 296, E. Valenta brought before the notice of chemists a new test for oils; this consisted in mixing equal volumes of the oil and glacial acetic acid of 1·0562 sp. gr., heating the mixture until solution occur, and then introducing a thermometer into the mixture and allowing it to cool slowly, and noting the point at which a turbidity begins to make its appearance in the tube. An abstract of this notice appears in the *Chem. Soc. J.* Abstracts, 1884, p. 1079; see also *J. Soc. Chem. Ind.* 1884, 642. In this paper Valenta states that olive and castor oils are soluble in glacial acid at ordinary temperatures, while rape oils are only imperfectly soluble, and other oils only dissolve in glacial acid when heated. The statement in regard to olive is not borne out by figures quoted in a table given with the paper.

More recently this test was brought before the notice of the members of the Manchester Section of the Society of Chemical Industry, in January last, by Mr. Alfred H. Allen, of Sheffield, and reported in the Journal for February, 1886.

I have at odd intervals made a few experiments with this test, but without any very satisfactory results; recently, however, I have had an opportunity of examining a large number of samples of various oils with this test, and as the results I obtained differed from those obtained by Valenta and Allen, I thought it might be of interest to the members of this Section to bring them before you.

In the original paper, beyond stating that equal volumes of oil and acid are used, Valenta mentions no specific quantities to be taken; Allen recommends using 3cc. of each. My experiments were made as follows: 5cc. of oil were poured into a test tube, and 5cc. of glacial acetic acid, sp. gr. 1·0562, were added. A thermometer was then inserted into the mixture and the whole heated until a clear solution was obtained. The mass was then allowed to cool slowly, and the temperature, when the mixture became turbid, was noted.

My results are given in Table I., and as far as comparison is possible, the corresponding figures of Valenta and Allen.

It will be observed from the figures given that Allen invariably gives lower turbidity temperatures than Valenta, and that my temperatures are lower than either of those observers.

There is also another important difference between us; both Valenta and Allen state that rape oils are not soluble, even at the boiling point of acetic acid. Now, I was always able to dissolve these oils.

From the figures given it will be seen that rape and colza oils have a high turbidity temperature; linseed oil is comparatively low in the list; while castor oil and oleic acid dissolve easily at the ordinary temperature. Olive oil is intermediate between rape and linseed, and it is notable that tallow oil has a lower turbidity temperature than the corresponding lard oil. This test will be found useful in detecting rape oil in admixture with other oils.

From the differences in the turbidity temperatures of the same oils obtained by Valenta, Allen, and myself, it seems to me that we might infer that a considerable amount of personality enters into this test, a great deal depending on the manner in which this test is carried out. I have obtained various figures even with the same samples of oil and acid. To

obtain good results it is necessary to have a *dry* test tube: the presence of a *small* quantity of water increases the turbidity temperature, or in the case of rape and colza oils prevents their being dissolved.

This seems to show that while the test is useful in many cases, it must always be carried out in one particular manner, and as a comparative test in the same manner as Maumené's test is used.

On reference to Table I. it will be noticed that even samples of the same kind of oil differ among themselves sometimes to a great extent, as, for instance, the olive oils from 76 to 28.

TABLE II.

SHOWING INFLUENCE OF FREE ACID ON THE TURBIDITY TEMPERATURE.

,, Gallipoli	28	22·06

On thinking over what may be the reason of this difference, I felt inclined to adopt a suggestion of Mr. Allen's, that difference in the amount of free acid that oils would contain would lead to differences in the turbidity temperatures of such oils.

Now, seeing that oleic and acetic acids are miscible at the ordinary temperatures in all proportions, I thought that it would be safe to infer that the greater the proportion of free fatty acid an oil contained, the lower the turbidity temperature would be; to see whether this inference was correct, I determined the amounts of free acid present in the oils, and the results are given in Table II. But the evidence is nearly as much against as for this inference.

I therefore made a number of direct experiments. I took 5cc. of cotton oil (because this contained the least amount of free acid of all the oils examined) and mixed it with varying quantities of oleic acid, and determined the turbidity temperatures of these mixtures; the results are appended:—

	Turbidity Temperature.
5cc. cotton oil ½cc. oleic acid	18°
5cc. cotton oil 1cc. oleic acid	37
5cc. cotton oil 1½cc. oleic acid	28
5cc. cotton oil 2cc. oleic acid	20
5cc. cotton oil 2½cc. oleic acid	15

From which it will be seen that the turbidity temperature decreases with increase of oleic acid, and that when the proportion of acid in the oil gets to 33 per cent. it is practically soluble at the ordinary temperature of the air.

I am strongly inclined to think that the inference as to the effect of acid in oil on this test noted above is correct.

In connection with my experiments I made a few to see what influence varying the quantities and proportions of oil and acid would have on the results.

I found, first, that so long as the proportions of oil and acid remained the same it did not matter how much of each was taken. If the proportions were altered I found the results affected as follows: Increase of oil decreased the temperature of turbidity, while increase of the acid increased the temperature. Table III. shows some of the results obtained in this way.

Mineral oils are only partially soluble in acetic acid at 50° C., while rosin oil is completely soluble; thus this test can be used to distinguish these oils, but it cannot be used quantitatively.

When a mineral oil and a fat oil are mixed together, the mixture containing about 10 per cent. of mineral oil and treated with acetic acid, the oil is completely dissolved, the presence of the fat seeming to bring about the solution of the mineral oil; if the proportion of mineral oil be much greater than this, then complete solution does not occur.

Since writing the above paper Mr. Ellwood has published (*Pharmaceutical Journal*, 3, xvii. 519) some results of his in the use of this test, in which he corroborates some of my remarks. He gives the following figures:—

Olive oil	101° C.
Almond oil	108° C.
Linseed oil	67° C.

DISCUSSION.

Mr. Thomson desired to know what was the nature of this turbidity, and also if all the oil would separate out at the ordinary temperature of the atmosphere; further, which test Mr. Hurst considered the better—the acetic acid or the ordinary sulphuric acid test? Had Mr. Hurst determined the amounts of different oils dissolved by the acetic acid at the ordinary temperatures?

Mr. McNair said he might suggest that some of the discrepancies arose from the manner in which the experiments were carried out, for the thermometer did not give the true temperature of the liquid. A thermometer with a large bulb would cool more slowly than one with a small one, and would therefore give too high a temperature. He would suggest that the tube containing the mixture of oil and acid should be immersed in a large volume of heated liquid, which would then cool down slowly and give the true temperature.

Mr. Hurst: In reply to Mr. Thomson's question as to turbidity, he should regard it simply as a deposition of the oil from the acid. He had allowed the mixture of oil and acid to stand for some time, and then found that they gradually separated into layers, the oil above and the acid below. It seemed to him that the solubility depended upon the temperature, and hence there was a difference in turbidity and temperature with different oils according to their degree of solubility in the acids. With regard to the comparison between this test and Maumené's, he considered Maumené's the best. As to the manner in which these experiments had been carried out, he had tried the experiments in the form given by Mr. McNair, and had found no advantage over the method described. The results were much the same.

CLAUS'S PROCESS FOR THE PURIFICATION OF COAL-GAS BY AMMONIA.

BY C. W. WATTS.

The process which I have to describe has for its object the complete purification of coal-gas in closed vessels. It is founded on the processes invented some years ago by F. C. Hills, which had the same object in view, but have not succeeded completely, although a portion of the process has been in use for a considerable time at the Old Kent Road works of the South Metropolitan Gas Company.

The material which we use for purifying the gas is ammonia, which is employed in the form of gas. As all the impurities of coal-gas are, with the exception of ammonia itself, of an acid character, they are removed in combination with ammonia, dissolved in water. For the purpose of description the process may be divided into three parts, and I will first briefly describe the apparatus employed in the different stages of the process.

For the purification of the gas a series of six scrubbers is employed; they are shown on the plan at A, A_1—A_5.

Five of the scrubbers are 4ft. square and 20ft. high, the sixth (a subsequent addition) is circular, 5ft. diameter and 30ft. high. The total scrubbing space is about 2000 cubic feet, which allows 8 cubic feet space for each 1000 cubic feet of gas purified per diem, reckoned on the maximum make.

All the scrubbers are filled with broken gannister brick, in pieces about 2in. in diameter, and are provided with tumbling boxes for distributing the liquor.

At the foot of each scrubber is a pump, by which the liquor from each scrubber is sent into another. The last scrubber, A_5, is supplied with cold spent liquor from the still, in quantity regulated according to the amount of gas passing through the system; this liquor is pumped from one scrubber to another through the entire series, gradually taking up the impurities from the gas, until it is finally removed from A, saturated with these impurities, and ready for the next stage of the process.

The second stage of the process is that known as Hill's process, and consists in the decomposition by heat of the carbonate and sulphide of ammonia contained in the scrubber liquor, the carbonic acid and sulphuretted hydrogen being expelled, while the ammonia is retained in the liquor.

The plant consists of three parts:—1st, the apparatus in which the actual heating takes place; 2nd, a scrubber, which we call a carbonating tower, in which the gases from the heated liquor are washed with the cold scrubber liquor on its way to the heating tower; and 3rd, a small catch scrubber for completing the absorption of the ammonia which accompanies the carbonic acid and sulphuretted hydrogen.

In the experimental plant at Windsor Street the heating apparatus and the carbonating tower are each divided into two portions, but they really form one apparatus, and will be so described. The catch tower B and the carbonating towers B_1 and B_2, are constructed and worked just like the scrubbers; they are 2ft. square and 18ft. high.

The heating is effected in the two towers marked

B_3 and B_4. These are also 2ft. square and 18ft. high; each is fitted with thirty cast-iron trays 22in. square and 3in. deep, in each of which is a flat coil of ¾in. steam pipe supplied with steam from a main pipe between the two towers. The scrubber liquor, after passing through the carbonating towers B_1 and B_2, is pumped to the top of B_3 and overflows from tray to tray to the bottom, where it is pumped to B_4 and passes in the same way through this, the temperature gradually rising and more and more of the carbonic acid being driven off, until at the end the liquor consists principally of caustic ammonia, and is ready for the next process.

This is carried out in two towers marked C and C_1, similar in all respects to the carbonating towers, and forming, as they do, a single piece of apparatus. A third tower C_2, in connection with them, acts as a condenser for the hot gases from C_1.

The purified liquor from B_4, which is already at a temperature of 195° F., is pumped into C_1 and thence to C. At the bottom of C free steam is introduced (as a matter of practice the exhaust steam from the engine is used).

It is at this point that the portion of the gas which is purified in our plant is drawn off.

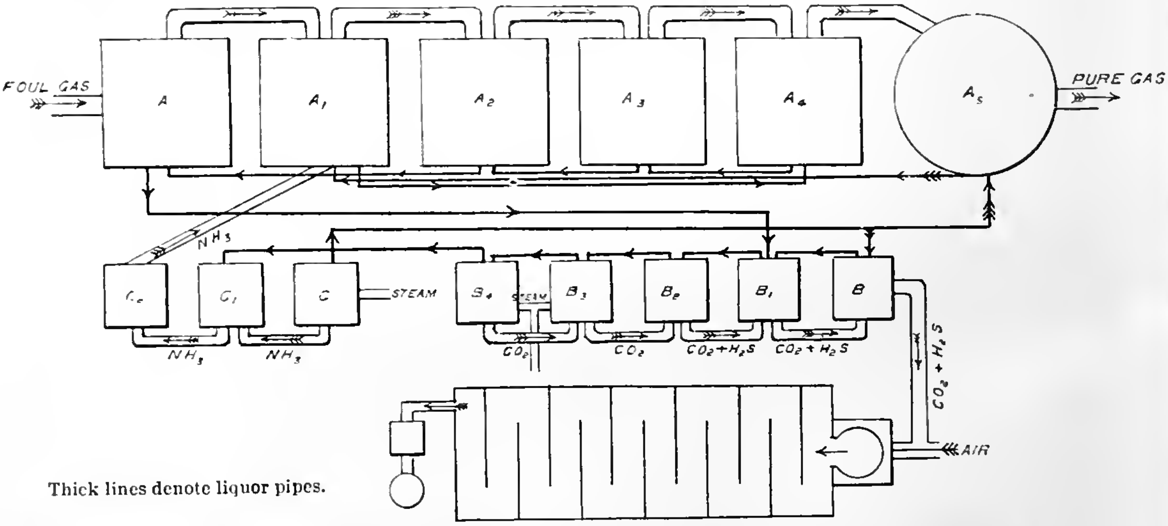
The gas entering the scrubbers contains the following removable impurities:—Ammonia, sulphuretted hydrogen, carbonic acid, and carbon bisulphide, and, in addition, hydrocyanic acid and oxygen, which, though they can hardly be called impurities, are absorbed in the scrubbers, and play an important part in the process.

The quantities of these substances are, as might be expected, somewhat variable, as will be seen from the following table:—

Ammonia	0·4 to 0·5	per cent.	by volume.
Sulphuretted hydrogen ..	1·0 to 1·8	,,	,,
Carbonic acid	1·5 to 2·8	,,	,,
Hydrocyanic acid	0·1 —	,,	,,
Oxygen..................	0·0 to 0·8	,,	,,

The volume of the carbon bisulphide is extremely small, only forming two or three hundredths per cent. of the crude gas.

The carbonic acid and sulphuretted hydrogen generally amount to about four per cent. of the crude gas.



Thick lines denote liquor pipes.

A minute quantity of caustic soda solution is mixed with the liquor in the still for the purpose of decomposing the fixed salts of ammonia. The liquor, on arriving at the bottom of C, is completely free from ammonia, and, after cooling, is pumped to a tank placed over scrubber A, and is used again for washing the gas.

The whole series of operations is perfectly continuous; the only materials used for the purification of the gas are ammonia and water, which are brought together in the scrubbers to combine with and absorb the impurities of the gas, and are then, after being freed from these impurities by heat, separated from each other by distillation, to be again brought together in the scrubber, and so on.

We will now consider more in detail the changes undergone by the gas and liquor in the various stages of the process.

PURIFICATION OF THE GAS.

The crude gas made in the retorts passes first through the condensers and a Livesey washer, the latter being supplied with liquor from the condensers. In these it deposits the tar and the excess of water, and the condensed water absorbs about two-thirds of the ammonia in combination with carbonic acid and sulphuretted hydrogen.

We find that, under ordinary conditious, the liquor produced in the scrubbers consists, empirically, of normal carbonate and hydrosulphide of ammonia; consequently, to effect complete purification, we must supply to the gas a quantity of ammonia equal to twice the volume of the carbonic acid + once the volume of the sulphuretted hydrogen, or, deducting the ammonia already contained in the gas, about 6·5 per cent. by volume of the foul gas, or nearly 30lb. of ammonia for the gas produced from one ton of coal.

We have found it most advantageous to work with a liquor containing about four per cent. of ammonia, of which about three-fourths is causticised in the subsequent heating process and rendered available for purification. It follows that about 100 gallons of this liquor are required for the purification of the gas from one ton of coal. This quantity will, of course, vary with the amount of impurity, and also with the temperature, a smaller quantity being required in winter, and a rather larger quantity in warm weather.

I shall have to describe two modifications of the process; the first and more simple effects the removal of the carbonic acid, sulphuretted hydrogen and ammonia, with only a partial reduction of the carbon bisulphide, while by the second this impurity can be reduced to any degree that may be desired.

In the first method the spent liquor for washing the gas is introduced into the last scrubber; after passing through this it is pumped to the next scrubber, and so on straight through the series.

The foul gas enters at the bottom of scrubber A and passes straight through in the opposite direction to the liquor.

The ammonia for purification enters the system at the outlet of scrubber A and passes with the coal-gas through the connecting pipe to the bottom of A_1, the two being thus thoroughly mixed.

The foul gas entering A meets in its upward passage with the liquor produced in the next scrubber A_1. This liquor contains about five per cent. of ammonia, of which about three per cent. is combined with sulphuretted hydrogen (as monosulphide), and about one per cent. with carbonic acid, which accompanies the ammonia from the still.

As the ammonia from the still is necessarily somewhat warm, this liquor is at a temperature of 100—110° F., and when it comes into contact with the gas in A, some of the free ammonia and ammonium sulphide are volatilised and return to A_1, the effect being to always keep a stock of ammonia in the intermediate scrubbers, which is amply sufficient to deal with any temporary variations in the quantity of the gas or the amount of impurity contained in it.

In scrubber A, the whole of the carbonic acid is generally absorbed, but none of the sulphuretted hydrogen; indeed, the gas leaving the scrubber is richer in this impurity than the original gas, the additional quantity having been volatilised from the liquor.

At exceptionally low temperatures, and also with weaker liquor than is usually employed, the reverse is the case, the sulphuretted hydrogen, owing to its greater solubility in water, being absorbed first, while the carbonic acid passes forward. As before mentioned, the ammonia for purification enters at the outlet of the first scrubber, and passes together with the partially purified gas into the second scrubber A_1. In our first experiments, the ammonia was introduced with the foul gas into the first scrubber, but it was found that, owing to the great solubility of ammonia, the liquor produced contained a large proportion of free ammonia, which was in consequence wasted for purposes of purification. By introducing the ammonia into the second scrubber, and washing the foul gas with the liquor so produced, it is completely saturated with acid impurities. The gas entering A_1, thus contains about 10 per cent. of ammonia, two per cent. of sulphuretted hydrogen, and the small quantity of carbonic acid which accompanies the ammonia from the still. In its passage through this scrubber it is deprived of all the carbonic acid, and a large proportion of the ammonia and sulphuretted hydrogen.

In the next scrubber nearly all the remaining sulphuretted hydrogen is absorbed, and the remaining scrubbers complete the absorption of the ammonia.

In this process only five scrubbers are employed, and are worked so that the liquor from the last one, A_4, contained nothing but traces of ammonia, and that from A_3 contained from one to two per cent. of ammonia, and a trace only of sulphuretted hydrogen.

A typical set of liquors would be as follows:—

	A_4.	A_3.	A_2.	A_3.	A.
Total Ammonia	0·1	1·5	3·5	5·0	4·0
Sulphuretted Hydrogen	—	0·1	1·5	2·0	1·5
Ammonia as Carbonate	—	—	—	1·0	3·0

The foul gas always contains some oxygen, derived from air accidentally drawn in during the drawing and charging of the retorts. In its passage through the scrubbers some of this oxygen acts upon the ammonium hydrosulphide in the liquors and converts it into bisulphide:—$2NH_4HS + O = (NH_4)_2S_2 + H_2O$. On the quantity of bisulphide (polysulphide) thus formed depends the quantity of carbon bisulphide that is absorbed; but the quantity formed from the oxygen naturally contained in the gas is too small to effect more than a very partial purification of the gas from this substance. We attempted to increase the amount by introducing an additional quantity of air, but found that the absorption of oxygen by the liquor was so slow and incomplete that it would have been necessary to introduce so much air as to seriously reduce the illuminating power of the gas.

We then adopted the present system of dissolving the necessary amount of sulphur in the liquor containing ammonium sulphide, and this method is successful in reducing the total sulphur compounds below the maximum allowed by the London Referees.

As carbon bisulphide vapour is, even when undiluted, practically insoluble in water, it is evident that, when it forms, as in the case of coal gas, only two or three hundredths per cent. by volume of the gas, it may be regarded as absolutely insoluble, and its removal by a liquid absorbent must be effected, as it is by solid absorbents such as calcium sulphide, by exposing a large surface of the purifying material to the gas.

For this reason we have found it necessary to increase the scrubbing power by the addition of a sixth scrubber, and to devote three of the scrubbers to this work, supplying them with the liquor containing ammonium bisulphide.

The course of the liquor through the scrubbers has therefore been altered, that of the gas remaining as before.

The wash water is pumped into A_5; from this it passes at once to A_1, the scrubber into which the ammonia first enters. Here it absorbs ammonia and sulphuretted hydrogen, and is then pumped into A_4. Before coming into contact with the gas in this scrubber, it passes through a quantity of sulphur and dissolves some of it, forming the necessary polysulphide.

From A_4 the liquor passes to A_3, from A_3 to A_2, and thence to A.

The carbonic acid is, as before, absorbed in A, the bulk of the ammonia and sulphuretted hydrogen in A_1, while the next three scrubbers, which are already charged with a liquor strong in sulphide of ammonium, absorb little of the principal impurities, which pass through them to A_5, where the purification is completed.

The carbon bisulphide is, for the most part, absorbed in the three scrubbers A_2, A_3, and A_4, which contain the polysulphide.

Since the adoption of this system, the total sulphur in the gas purified by our process has never exceeded 20 grains per 100 cubic feet.

By further increasing the size of the scrubbers this quantity could be reduced in proportion.

The gas is continually tested during the day with Harcourt's apparatus, and the highest result obtained was 12·5 grains S as CS_2, while many results below 5 grains have been recorded. The reliability of these tests has been confirmed by the Referees' test for total sulphur, the average of a number of tests being 16·9 grains, with a maximum of 19 grains.

Temperature does not appear to have any direct effect upon the absorption of the carbon bisulphide, but indirectly affects it by varying the composition of the liquors, a higher temperature causing the accumulation of ammonium sulphide in the intermediate scrubbers.

The only conditions necessary for the efficient purification of gas from carbon bisulphide are sufficient surface of liquor exposed, and enough polysulphide to keep the liquor distinctly yellow on its emergence from scrubber A. This amount is about 0·25 to 0·3 per cent. (weight in volume), of which about one-half is due to the oxygen of the foul gas, and the rest is obtained by the direct addition of sulphur.

In passing through scrubber A some of this sulphur (about 0·1 per cent.) combines with ammonium cyanide to form thiocyanate, and a further portion (about 0·05 per cent.) is converted into thiosulphate. If the amount of sulphur as polysulphide is not sufficient to form these compounds, then the absorption of the carbon bisulphide is incomplete.

Hill's Process.

The scrubber liquor produced in our process is similar in composition to ordinary gas liquor. A typical sample had the composition :—

Ammonia	4·50 per cent.	Grams in 100cc., or lbs. in 10 gallons.
Sulph. hydrogen	1·08 ,,	
Carbonic acid	5·20 ,,	
Sod. Thiosulphate	0·50 ,,	
Sod. Thiocyanate	1·00 ,,	

The simplest way of expressing the proportions of ammonia, sulphuretted hydrogen and carbonic acid is this :—

Ammonia	4·50
Sulphuretted hydrogen	1·08
Ammonia as carbonate	1·00

The equivalents of ammonia and sulphuretted hydrogen being the same (17), this mode of expression shows that this liquor consists, empirically, of normal carbonate and hydrosulphide of ammonia.

The scrubber liquor is pumped into the carbonating tower B$_1$, and on its way down this and the next tower it meets with the gases evolved from the liquor in the heating towers. These gases consist of ammonia sulphuretted hydrogen and carbonic acid. In the upper portion of B$_1$, where the temperature is low, the ammonia is almost completely absorbed, and what little does not escape condensation is absorbed in the catch tower B.

At the same time as the liquor absorbs ammonia it also takes up, at first, some of the other gases, and the ammonium sulphide is gradually decomposed by the carbonic acid, the decomposition becoming more complete as the liquor becomes warmer.

At the bottom of B$_2$ the temperature of the liquor is 160—170° F., and the greater part of the ammonium sulphide has been converted into carbonate. The liquor also contains a good deal of free ammonia which has been volatilised from the heating towers.

From the carbonating tower B$_2$ the liquor passes to the heating apparatus B$_3$ and B$_4$. It will be remembered that this consists of a series of 60 trays heated by steam, the liquor overflowing from tray to tray. The steam is adjusted so as to raise the liquor to a temperature of 195° F. By this the excess of ammonia over that contained in the original liquor is expelled together with most of the carbonic acid, so that at the outlet of the apparatus the liquor consists principally of caustic ammonia.

The extent to which the decomposition of the ammonium salts may be carried depends on three things—time, temperature, and strength of liquor ; the longer the time, the higher the temperature, and the weaker the liquor, the further can the decomposition be carried. Our heating apparatus is of such size that the maximum quantity of liquor worked takes at least two hours to pass through it, being raised during that time from 160° to 195°.

A scrubber liquor containing about 4 per cent. ammonia as carbonate and sulphide under such circumstances loses at least three-quarters of its acid constituents. The composition of the liquor mentioned before would be about —

Total ammonia	4·50 per. cent.
Ammonia as carbonate	1·40 ,,
Sulphuretted hydrogen	nil.

Liquors containing less than 3 per cent. of ammonia can be heated to 200° F., and the amount of ammonia causticised will be from 80 to 90 per cent. The additional expense of heating the larger volume of liquor of this strength would, however, more than compensate for the slightly greater yield of free ammonia.

Distillation of the Purified Liquor.

The last stage of the process is that in which the ammonia is expelled from the liquor and returned to the scrubbers.

The liquor from the heating apparatus, which is at 195° F., is pumped into the still, which consists of two towers, and the exhaust steam from the engine entering at the bottom of the still expels the whole of the ammonia and ammonium carbonate from the liquor.

It will be recollected that the scrubber liquor, besides carbonate and sulphide, contains thiocyanate and thiosulphate ; these salts are not decomposed at 212°, so that it is necessary to add a fixed alkali in order to obtain the ammonia from them. In our plant at Windsor Street we generally employ caustic soda for this purpose ; on a larger scale, lime would of course be substituted.

The whole of the ammonia from the liquor, together with some steam and carbonic acid, which has not been expelled by the previous heating process, pass from the still through a third tower, which acts as a condenser. In this most of the steam and carbonate of ammonia are condensed, and the resulting liquor returns to the heating towers. The rest of the ammonia, still at a temperature of about 100°, passes from the condenser back to the scrubber A$_1$, thus completing the cycle of operations.

The spent liquor from the still is cooled and pumped back to the scrubber A$_5$ to be used again for washing the gas. The excess, due to condensed steam, and not required in the scrubbers, is continually withdrawn, and from it the thiocyanate is recovered.

The whole series of operations described goes on continuously, and is easily kept in order. A few points only have to be looked to in order to maintain purification. The amount of ammonia supplied to the scrubbers must be sufficient, but not greatly in excess of that required to combine with the impurities. In order to regulate this, the gas must be tested at one or two points, easily found by experience, which the different impurities should reach, but not pass. If the ammonia is found to be in excess or the reverse the quantity is altered by increasing or diminishing the amount of wash-water (spent liquor) supplied to the last scrubber. As there is always a surplus of spent liquor produced there is always enough for any slight increase that may be required. It will easily be understood that an increase (or decrease) of the amount of water in the last scrubber means an increase in the liquor from scrubber A, which, passing through the heating and distilling plant, means an increased supply of ammonia to the scrubbers. Even considerable variations of the quantity of water supplied to the scrubbers do not appreciably affect the strength of the liquor ; the only effect is to vary the rate of circulation, and therefore the amount of ammonia entering the scrubbers in any given period of time.

The other points that require attention are the temperature of the heating apparatus and the still. With a regular circulation of the liquor and a tolerably uniform pressure of steam, these require very little attention: of course, if the quantity of liquor passing through the plant is altered, the steam must be altered in proportion.

It still remains to describe the method by which sulphur is recovered from the gases evolved by heating the liquor, and to mention the methods by which it is proposed to recover thiocyanates, and to obtain the ammonia of the foul gas in forms more valuable than ordinary gas liquor.

The foul gas entering the scrubbers contains carbonic acid and sulphuretted hydrogen, amounting together to about 4 per cent. of the volume of the gas. The ratio of the carbonic acid to the sulphuretted hydrogen is about two to one.

A small quantity of the sulphuretted hydrogen is oxidised, and the sulphur unites with hydrocyanic acid, but the greater part it, and the whole of the carbonic acid of the foul gas, pass out of the catch tower B.

The gas consists of about 25 to 30 per cent. sulphuretted hydrogen, and the rest is carbonic acid, with a trace of hydrocarbon vapour.

The process employed for recovering the sulphur is that invented by Mr. Claus, and now in use at several places in connection with the manufacture of sulphate of ammonia.

The apparatus consists of what we call a kiln, a depositing chamber, and catch purifiers as a safeguard against the possibility of a nuisance.

The kiln is a small chamber built of fire-brick, and enclosed in a shell of cast-iron plates. The chamber in our case is circular, 2ft. 6in. in diameter, and 3ft. high; it contains a layer, 15in. deep, of oxide of iron in lumps about 1in. diameter, supported on a grating built of 1in. split fire-bricks set on edge. A space of about 1 foot above the oxide is empty, and the gas enters this space, passes downwards through the oxide and out from below the grating into the depositing chamber. This is a brick building, 24ft. long by 8ft. wide and 5½ft. high, with 9in. walls and flat roof of ¾in. slates. Transverse baffle walls are built inside the chamber, which open alternately on one side and the other of the chamber, so that the gases are forced to traverse the whole area of the chamber before reaching the outlet.

Previous to entering the kiln the gases are mixed with a quantity of air (supplied by a small air-pump) 2½ times the volume of the sulphuretted hydrogen. This volume of air contains the oxygen necessary to convert the hydrogen of the sulphuretted hydrogen into water, thereby setting free the sulphur.

At starting, the kiln is filled with hydrated oxide of iron (manganese or other metal), the ordinary reactions take place between the substances present, sulphide of iron being formed and immediately reoxidised by the air, and, as these reactions take place in a small confined space, the heat produced accumulates until the whole mass is red-hot. At this temperature, of course, the sulphur produced by the reaction is immediately volatilised, and passes with the other gases into the depositing chamber, where it settles. As the proportion of sulphuretted hydrogen in the gas is not quite constant, it will generally happen that there is either a slight excess or a slight deficiency of air supplied. There will then be a small quantity of either sulphuretted hydrogen or sulphurous acid at the outlet. To prevent the escape of these gases into the air, a wash tower filled with pebbles and supplied with a little water is connected to the chamber, and beyond this is a small open oxide purifier. The water absorbs any sulphurous acid that may be present, and the oxide of iron any traces of sulphuretted hydrogen.

The sulphur obtained amounts to about 90 per cent. of the theoretical quantity. It is very pure, analysing over 99 per cent. sulphur, deducting the moisture that it generally contains. The gases from the gas liquor contain small quantities of naphthalene and other hydrocarbons, and these being charred in passing through the kiln impart a brownish tinge to the sulphur. The amount of carbon present, however, does not amount to 0·1 per cent.

THIOCYANATES.

Hydrocyanic acid exists in the foul gas to the amount of about 0·1 per cent. by volume. It is absorbed by the liquor, and combines with sulphur to form thiocyanic acid; $NH_4CN+(NH_4)_2S_2 = NH_4CNS+(NH_4)_2S$. If there is not sufficient polysulphide present to convert all the hydrocyanic acid into thiocyanic acid the rest remains unaltered until it reaches the heating apparatus, where at least some of it acts upon the iron of the apparatus and forms ferrocyanide.

The ammonium thiocarbonate, formed by the absorption of carbon bisulphide, also forms thiocyanate by spontaneous decomposition, $(NH_4)_2CS_3 = NH_4CNS+2H_2S$. The thiocyanide thus formed is converted into sodium salt by means of caustic soda added in the still, and is found in the surplus spent liquor derived from the condensed steam.

The amount of sodium thiocyanate formed is 2·3lb. per ton of coal.

From the spent liquor the thiocyanate is recovered, either by simple evaporation or by precipitation with cupric sulphate or cuprous thiocyanate.

From the sodium salt ferrocyanide may be made by Gelis's process.

AMMONIA.

It will be understood from the general description of the process that a certain stock of ammonia is constantly circulating through the system. The amount required is estimated at about 50lb. ammonia in the plant for each ton of coal carbonised per diem.

As the foul gas entering the scrubbers contains ammonia, equal to about 1½lb. per ton of coal, an accumulation would take place, unless an equal quantity was continually withdrawn. Of course this withdrawal may be effected in the form of ordinary gas liquor from scrubber A, but the process allows of its withdrawal in either one of two more valuable forms, sulphate and carbonate.

The manufacture of sulphate in connection with the process could readily be effected by substituting an acid saturator for the catch tower B, attached to the heating apparatus.

As the quantity of ammonia normally entering this tower is less than that which must be withdrawn, a connection is made from a part of the carbonating tower where, in consequence of the higher temperature, the gases contain a larger proportion of ammonia. By this means the amount of ammonia withdrawn may readily be made equal to that brought in by the foul gas, and at the same time the acid saturator would act as a perfect safeguard against the escape of any ammonia with the other gases.

If sulphate were made in this way the whole of the fuel, and all the plant, except the saturator, would be saved, the sulphate being manufactured for the cost of the acid and the labour.

In the description of the action of the heating and carbonating plant it was explained that the sulphuretted hydrogen was expelled from the liquor by the carbonic acid evolved in the heating tower. At or about the junction between the heating and carbonating towers the gases in the apparatus are ammonia, carbonic acid, and steam.

If these gases, or a portion of them, are conducted into a cold chamber there condenses a liquor, which on cooling, forms a mass of crystals of ammonium carbonate. The mother liquor usually contains a little sulphide, but the crystals are free from it. A specimen of such condensed liquor contained 24 per cent. of ammonia, of which 18 per cent. was carbonate, and only 0·6 per cent. of sulph. hydrogen.

This is equal to a liquor of 110oz. strength, or say ten times the strength of ordinary gas liquor.

I have now described the whole number of operations involved in this process of purification, and it may be useful to re-state the essential features of the process and point out the advantages which it offers over the ordinary process.

The most important feature of the process is that it effects complete purification of the gas by a perfectly continuous operation carried out in closed vessels. There is no possibility of nuisance arising from the opening of purifiers containing foul gas, or the exposure of the purifying material to the air, nor any loss of gas or admixture of air with the gas from the former cause.

The gas is completely purified from carbonic acid and sulphuretted hydrogen, from all but the usual traces of ammonia, and the obnoxious and troublesome carbon bisulphide is easily reduced to any desired amount by a simple and cheap addition to the ordinary process.

The illuminating power of the gas is not reduced by this process: indeed the average of a large number of tests showed a slight excess of illuminating power over that of the same gas purified by lime and oxide. This may be ascribed to the complete absence of carbonic acid, and perhaps also to the fact that a smaller proportion of the oxygen is absorbed.

The by-products, sulphur and ammonia, are recovered in more valuable forms, and thiocyanates, which may fairly be called a new product, at least as far as English gasworks are concerned, are easily recovered and converted into valuable salts. The ground space covered by the plant is less than that required for dry purification, especially where sulphur purification is carried out.

The cost of working I am hardly prepared to state, as the expenses of ordinary work cannot be calculated from that of an experimental plant, where the attendance and labour required for continual alterations are much greater than would be required for regular work.

The principal expense is for fuel in raising the necessary steam; the cost of this has been 2½d. per ton, taking fuel at five shillings per ton. It may reasonably be expected that considerable economies will be effected on this side; and especially the possibility of raising steam by means of the waste heat from the retort furnaces must not be lost sight of.

The amount of sulphur required to form polysulphide for the purpose of removing carbon bisulphide from the gas is about 2lb. per ton of coal. Taking sulphur at £4 per ton this would be 0·85d. per ton of coal, or 0·085d. per 1000 cubic feet. The cost of sulphur purification in London is given by Mr. F. Livesey at 1¾d. per 1000 cubic feet.

DISCUSSION.

Mr. Hack: We have been listening to a very interesting paper, and are very much indebted to Mr. Watts for the clear way in which he has described the process. A question I wish to ask is as to the alleged cost of ordinary purification. It was stated to be 1¾d., whereas I have reason to believe it is covered entirely by 1d. per 1000 cubic feet. I may say, that being in Birmingham I have had the opportunity, from time to time, of following out this very interesting process, and consider that much praise is due to Mr. Claus in respect to it, and should be glad to hear that we shall be able to purify our gas by the process as cheaply as we do at the present time. I am not prepared to contest anything that Mr. Watts has said with regard to the chain of beautiful chemical changes and reactions which take place; but I may state that on the last occasion when tests were made on my behalf the process was not efficient for reducing regularly the sulphur compounds to the desired limit, and I am therefore very pleased to hear that by the addition of sulphur to the liquor he has been successful in bringing them down to a very low point, and well within the limits prescribed by the London gas refiners. This is a very important point, and one that will weigh well with gas engineers; but, as a gas engineer, I should like to be assured, before adopting the process, that taking the value of the extra products—Prussian blue, etc.—into account there would be a saving over the prevailing method. For the last three years, at one of my works, we have been able to purify the gas from carbonic acid, sulphuretted hydrogen, and ammonia, and bring the sulphur compounds down very low; the whole cost, including new materials and labour (after crediting the materials sold), has not exceeded one-third of a penny per 1000 cubic feet of gas made. Now that is a very small item, and I repeat that we want to be assured that by this new plan we should be able to purify cheaper than this. I am not going to say anything against this beautiful chemical process, but we now wish to have some reliable information as to the net cost. Without considerable saving can be shown to result, this system will I hardly think take the place of our existing purifying arrangements, but it is more likely to be adopted where new works are contemplated, or extensions required, as at Belfast; and we shall all anxiously await the results obtained there upon the larger scale.

Mr. Watts: In actual practice it is impossible to use extremely concentrated solutions, on account of the rapid volatilisation of the ammonium sulphide. We have in the laboratory used such a solution containing polysulphide with good effects. I may say that I have made a number of experiments with different sulphides, more particularly barium and sodium sulphides, and I have found that solutions of monosulphides, unless very strong, are absolutely incapable of absorbing bisulphide of carbon. The conclusion I came to was, that the monosulphides are decomposed in solution into hydrate and hydrosulphide, and it is well known that hydrosulphides will not combine with carbon bisulphide. When the solution is very concentrated this decomposition will be incomplete, and the carbon bisulphide is then absorbed by the undecomposed monosulphides. The formation of a small quantity of polysulphide, either by addition of sulphur or by exposure of the solution to the air, at once confers upon the solution the property of absorbing bisulphide of carbon. The case of ammonium sulphide is somewhat different to that of barium and sodium sulphides. Monosulphide of ammonia only exists at very low temperatures, so that even very strong solutions, so long as they are free from polysulphide, will not absorb carbon bisulphide. The use of polysulphide of ammonia was discovered by Leigh, at Manchester, some years ago. How far the invention was carried into practice I cannot say. Mr. Turner asked about the effect of oxygen upon the illuminating power of gas. I mentioned that the oxygen in the foul gas was only partially absorbed in our process, and stated that this would be rather an advantage than otherwise. Dr. Frankland has proved that the reduction of the illuminating power of gas by the presence of air is due to the nitrogen, the oxygen tending to counterbalance the injurious effect of the nitrogen, doubtless by increasing the temperature of the flame. Consequently, given the unavoidable presence of a certain proportion of air, a process which does not absorb the oxygen is preferable to one that absorbs almost the whole of it. Then as to the additional cost of the removal of the sulphur compounds. The cost in London is given by Mr. F. Livesey as a 1¾d. per 1000 cubic feet; very likely this has been reduced since the date of his paper on the subject. In our case it is about 1d. for 10,000 cubic feet.

The Chairman: The question of purification in closed vessels is one that has occupied the minds of gas men for many years past, and many attempts have been made to arrive at a solution of it. About eleven years ago success was thought to have been achieved by Hill's process, by which ammonia is driven from its combination with other impurities in gas liquor, and used over again in the washers or scrubbers. Only partial purification, however, was effected by this means, and, substantially, little was accomplished until the matter was taken up by Mr. Claus, by whom complete purification, without the aid of any foreign material, has at length been effected. Hitherto we have regarded this as an object to be attained, not as a means for increasing the value of the residual products, but almost solely for the reduction of labour, the avoidance of the necessity for costly plant, and for doing away with the loss and nuisance resulting from the emptying and charging of dry purifiers. The operations of the Ammonia Purifying Co., however, while embracing all these objects, have revealed to us new sources of income, not only from the more saleable character of the residuals, but also from the addition they are able to make to the latter, in the utilisation of the sulphocyanides which have hitherto been run to waste. It is, therefore, greatly to be desired that the process may be successfully developed, and those who, from the data already furnished by the experiment, have determined upon adopting it on a larger scale, deserve our thanks for affording the only possible means by which its economical advantages can be fully and satisfactorily determined. In the observation made by Mr. Hack, as to the average cost of purification to the London companies being about 1d. per m., doubt was expressed as to the accuracy of Mr. Watts' statement of cost for the removal of the sulphur compounds—viz., 1¾d. per m. This, as stated by Mr. Watts, was given upon the authority of Mr. Livesey, and does not appear to me to be necessarily inconsistent with the statement of total cost; because Mr. Livesey was, I presume, speaking of the removal of sulphur compounds only, whereas the entire process of purification embraces at least one operation which is, or has frequently been, a source of profit—I refer to the removal of sulphuretted hydrogen by oxide of iron. If the oxide of iron be well bought the value of the spent oxide may become, as was frequently the case until recently, considerably greater than the first cost of the material. Mr. Hack referred also to the fact that at one of his works the cost of purification was extremely low, while at the same time the sulphur compounds never exceeded, but were frequently considerably within, the limits prescribed by the gas referees. Without special purification that was a very exceptional experience, and I think that the statement ought to have been supplemented by information as to how much of such a result was due to the process of purification employed; because it might very possibly be due simply to the employment of moderate heats, or to the use of a coal exceptionally free from sulphur, or to a combination of these causes. In any case it could prove nothing, either for or against the adoption of the ammonia process under such conditions, the advantages of which were not to be measured by the question of a few grains, more or less, of sulphur left in the gas. Having had the process working under my immediate supervision for some considerable time, I am in a position to say that for works of large size there is almost certain to be a considerable reduction on the cost of labour; although where the make of gas is small I should hesitate to recommend its adoption, for the simple reason that the labour required to work a plant for the purification of one million cubic feet per day would, in all probability, be equal to one of four or five times the dimensions. Mr. Watts has dealt fully with the prospect as regards increased value of residuals, and I need only add that, with respect to sulphur alone, which is recovered in a solid form, the return ought to be doubled, while the cost of oxide of iron and lime would entirely disappear.

MR. J. NEILSON CUTHBERTSON IN THE CHAIR.

ON WASTE GAS FROM OIL STILLS.

BY GEORGE BEILBY, F.I.C., F.C.S., AND J. B. M'ARTHUR.

Our attention has for some time been directed to the production of permanent gas, which invariably occurs at the later stages in the redistillation of crude shale oil and petroleum. The oil we shall refer to in this paper is crude shale oil, as it comes from the condensers of the retorts, containing, therefore, naphtha, burning oil, intermediate oil, lubricating oil, and solid paraffins, and, in addition, basic and acid tars and resinous bodies of high boiling point. The crude oil on entering the oil refinery is handled in one of two ways—it is either distilled to dryness in a moderate current of steam, or it is first treated with weak sulphuric acid and caustic soda for the removal of a portion of the basic and acid tars, and is then distilled to dryness. In either case this first distillation is, more or less intentionally, a destructive distillation; the original oil thus produces an oil of lower specific gravity, which contains a smaller quantity of acid and basic tars, and is therefore more easily refined. A residue of pitchy coke remains in the still, and hydrocarbon gas, sulphuretted hydrogen, ammonia and water vapours pass away from the condenser of the still. There is evidently a breaking down of complex bodies containing carbon, hydrogen, nitrogen, oxygen, and sulphur, into simpler hydrocarbons, and the other products enumerated above. But the amount of destruction permitted must be most carefully regulated, as the paraffins and olefines of higher boiling point are very easily decomposed and destroyed, so that a distillation which would produce excellent results on the basic and acid impurities might be disastrous in its effects on the solid paraffins and viscous olefines. The amount of destruction to be permitted is influenced by the nature of the original shale, the system of retorting employed, and by the market prices of the various paraffin products.

Our principal object was to study the history of one of the secondary products of this destructive distillation—the hydrocarbon gas. As far as we can learn, no measurements of the volume or tests of the quality of this gas had been made by other observers.

We have made experiments in the laboratory, distilling a litre, and in the works distilling about 10 tons at a time.

LABORATORY DISTILLATION.

A litre of crude oil was distilled to dryness in a glass flask over a Fletcher lamp, a current of low-pressure steam being passed through the oil during distillation. The gas from the condenser was drawn into a small gasholder. The entire distillate measured 985cc. The loss by volume was, therefore, 1·5 per cent.

Taking the weights of the oil and its products, we have :—

Crude Oil distilled		882grms.
Oil distillate	860·00grms.	
Residue	10·58 ,,	
Gas	7·93 ,,	
Unaccounted for	3·49 ,,	
	882grms.	

The volume of the gas was 6·85 litres, or at the rate of 1·1 cubic feet per gallon of oil. The illuminating power of the gas was 35 standard candles on a calculated consumption of 5 cubic feet per hour. It is a matter of general experience with oil works chemists, that in well-conducted laboratory distillations the amount of decomposition which takes place is small compared with that in works distillation.

WORKS DISTILLATION.

In January and February last year we made various determinations of the gas produced at the crude stills, in Oakbank Works. Through the courtesy of Mr. Fraser, the managing director of the company, we are enabled to quote some of these results here.

These experiments were made primarily to gain information as to the quantity and quality of the gas produced in actual distillation. Attempts were also made to measure the actual products from the crude oil so as to apportion the various losses as in the laboratory experiments, but in a going work it is absolutely impossible to get really trustworthy figures to a reasonable degree of accuracy. The large size of the vessels, the differences of temperature of the oil, the presence of water in the crude oil and distillate, all combine to prevent accurate measurement. We shall, therefore, only quote such portions of the results as refer to the gas evolved per gallon of crude oil.

The collection of the gas was effected by connecting the gas pipe of the condenser with a small gasholder about 20 feet in diameter. A steam jet was placed in the connecting pipe so as to draw the gas from the condenser and urge it forward to the holder. The gas on its way to the holder passed through a supplementary condenser, in which it was cooled to the temperature of the air, and deposited such naphtha and water as had escaped condensation in the ordinary condenser. All of the fittings were of a temporary description, and were ultimately found to be quite insufficient to pass the whole of the gas when it was at its maximum flow. In consequence of this only a portion of the gas could be collected, and the total make had to be estimated. The figures given below are certainly well within the truth.

A still charged with 2425 gallons of crude oil gave 2800 cubic feet of gas, or 1·15 cubic feet per gallon of oil.

A still charged with 2400 gallons of residues from the second distillation of crude oil gave about 4000 cubic feet of gas, or 1·66 cubic feet per gallon.

No systematic chemical examination of the collected gas was attempted, but its illuminating power was tested in a number of cases, and determinations of the amount of volatile hydrocarbons removable by scrubbing with heavy oil were made.

The average gas from the distillation, which yielded 1·15 cubic feet per gallon, had an illuminating power of 34 standard candles, calculated to a consumption of 5 cubic feet per hour. The average gas from the second residues, which yielded 1·66 cubic feet per gallon, had an illuminating power of 29 candles.

Samples of gas from various stages of the distillation were collected separately and tested for their illuminating power. It was found that gas began to come off freely when the distillate reached a sp. gr. of 890—from this stage till the yellow resinous end of the distillate began to make its appearance, the illuminating power was from 40 to 45 candles. During the running of the resinous distillate, that is, while the still was coking, the illuminating power fell to 24 candles.

By scrubbing with heavy oil, gas which had stood in the gasholder for 36 hours, 1·2 gallons of naphtha per 1000 cubic feet of gas was obtained. The illuminating power before scrubbing was 34 candles, and after scrubbing 22 candles. This shows that the gas is fairly permanent and might possibly be used for lighting railway carriages.

We did not chemically examine the naphtha separated by heavy oil scrubbing, but from its physical characters it seemed to consist chiefly of low temperature hydrocarbons. The comparatively high illuminating power of the oil-scrubbed gas seems to indicate that it probably contains some of the lower olefines.

We must point out that the experiments we have detailed were made with stills worked on the old non-continuous system. The recently introduced system of long-continued feeding certainly diminishes the decomposition of oil, and correspondingly reduces the gas production ; but, as we have pointed out at the beginning of the paper, regulated decomposition is one of the chief objects of the first distillation, and therefore a certain quantity of gas must always be produced. After due allowance is made for all reasonable deductions, there will still remain a large volume of excellent gas well adapted for the lighting of works and villages, and probably, also, of railway carriages. This is the more important to oilworks, as the practice of scrubbing the retort gas with heavy oil renders it absolutely useless for illuminating purposes.

DISCUSSION.

Dr. **Wallace** said the subject brought before them that evening was one which interested him very much, as it was the first time, so far as he knew, that this particular gas had ever been measured as regarded quantity or luminosity. He was very glad to hear that the illuminating power was so high. The gas obtained in the original distillation of the shale was much purer—perhaps 22 or 24 candles, and was, therefore, not so suitable for lighting towns or villages, or even railway carriages. Taking an ordinary work such as Mr. Beilby had been accustomed to, he would like to know what the quantity of gas per day would be, and whether this quantity would really be of some commercial value, for that really was the important point in the paper? If the gas could be turned to profitable account, his own impression was that it would do very well for compressing for use in railway carriages, although its illuminating power was not so high as the gas used at present.

Mr. **Stanford** asked how the gas stood compression, and whether it was easily condensed or not?

Mr. **Whitelaw** believed that Mr. Coleman had made some experiments in compressing gases of the kind under discussion. He remembered receiving a bottle of the oil, or compressed gas, which boiled with the slightest elevation of temperature; even the heat of the hand was sufficient to cause boiling. He was not aware, however, whether this was the same gas as Mr Beilby had operated on.

Mr. **Irvine** asked whether the amount of gas was decreased or increased by using steam in the distillation?

Mr. **Beilby**, in reply to Dr. Wallace's remarks, said that in a work like Oakbank the production of still gas would be about 20,000 cubic feet per day, but the production of some larger works would be from 80,000 to 100,000 feet. He had not had an opportunity of trying the effect of compression, as suggested by Mr. Stanford, but it was considered that oil scrubbing through a heavy oil was a much more severe test of the permanence of a gas than simple compression. Referring to Mr. Irvine's question, he had not tested the gas from stills worked without steam, but it was presumed that the production of gas would, in that case, be larger, because steam was used to prevent decomposition. Mr. Coleman's apparatus for the compression of gases, referred to by Mr. Whitelaw, was originally applied to waste gas from shale retorts. In that case the condensation of the very volatile hydrocarbons was due to the cooling by expansion in the working cylinder of the engine rather than to the preliminary compression.

(*A*) NOTES ON "NESSLERISING." (*B*) NOTES ON THE EXTRACTION OF FATS BY SOXHLET'S APPARATUS.

BY J. M. MILNE, PH.D.

In these notes originality is not claimed. They simply embody a description of some modifications of apparatus which I have found extremely useful in my laboratory.

"*Nesslerising.*"—Wanklyn's original instruction for nesslerising water distillates involved the taking over of three separate quantities of 50cc. and the determination of the ammonia in each. This involved a great deal of trouble, and occupied a considerable amount of time. Some years ago, Hehner suggested an improvement in this method, as well as in the form of nesslerising tube used, and I was so struck with the simplicity of his method, as well as with the great saving in time resulting from its use, that I at once ordered a pair of his nesslerising cylinders from London, and have used them ever since. Although these cylinders can now be had in Glasgow, I understand they are very little used, and this fact has induced me to bring them under your notice this evening. Hehner's modification of the original process is very simple and easily carried out. Instead of separate quantities, the whole distillate is collected in one. I have a series of stoppered bottles, holding over 200cc., which are kept specially for water distillates. These are marked for 50cc., 100cc., 150cc., and 200cc. In the case of a water containing little ammonia, 100cc. of distillate will be found to contain the whole of it. Others may require 150cc., or even 200cc. to be taken over. It goes without saying that in every case a final quantity of 50cc. must be collected separately and nesslerised, in order to ensure that the distillation is complete. One great advantage of this method is that with a number of waters on hand at one time, the distillations can be carried on one after the other, and the various distillates put aside and nesslerised when convenient, or the light most favourable.

The construction of the cylinders is also simple. They are made with a somewhat broad foot, and are graduated to hold 100cc. Near the bottom a glass tap is soldered on, so that the contents of the cylinder can be slowly run off. The two cylinders are placed side by side on a white surface, a measured quantity of standard ammonium chloride is run into one, then ammonia-free distilled water up to the 100cc. mark. 2cc. of Nessler's solution are next added, and the whole thoroughly mixed with a glass rod flattened out at the end. 100cc. of the water distillate is placed in the other cylinder, 2cc. of Nessler added and well mixed. In practice I find that 1cc. of standard ammonium chloride (= ·000025grm. NH_3) in 100cc. gives a tint which very readily can be compared. After standing for five minutes, the two cylinders are compared. If, as usually the case, the water distillate is the darker of the two, a small beaker is placed below its tap, which is then turned on till the contents drop out slowly. If the eye is directed straight down the interior of the cylinders, no perceptible movement of the column is observable, and a point will be reached when the tint of the contents of the two cylinders are alike. The tap is now closed and the height of the water distillate read off. It is then filled up again from the beaker, and re-adjusted. This is repeated three times and the average of three readings taken as correct. As nesslerising cannot be done in gaslight, I have endeavoured to imitate the process with two shades of indigo solution. Assuming that the lighter shade in this cylinder represents the standard ammonium chloride (and contains 1cc. of it) and that the darker one (the water distillate) has been run down to 70cc. to equalise the tint, then a simple proportion calculation is all that is required: If 70cc. contains ammonia equal to 1cc. of standard chloride, how much will 102 (the total bulk in the cylinder) contain? The rest of the calculations are obvious. It is evident that these cylinders can be equally well made use of in any kind of colorimetric testing. There is one slight objection to these cylinders as at present made. There are sometimes little specks in the glass at the bottom. This could easily be obviated by making the feet a little thicker, grinding them quite flat and then polishing, just like this small specimen-jar on the table. I am at present trying to get a pair of cylinders made to this improved pattern.

"*Soxhlet's Fat Extractor.*"—In the determination of fats, especially with regard to milk analysis, the use of this apparatus is very convenient and greatly to be recommended, and may, I think, entirely take the place of any other form of percolator. The arrangement on the table has been made according to my own instructions, and works very well. It has the advantage of enabling duplicate or separate determinations to be made side by side, using only one inverted condenser. The condenser is made flat or oval, instead of round, so that two internal tubes can be fitted in and a Soxhlet's extractor attached to the lower end of each. It is obvious that by making the outer case round and larger, four internal glass tubes can be used, and four extractions carried on at once, the whole arrangement being set up on a round table, so as to admit of easy access. I have on the wall an enlarged drawing of the actual Soxhlet part of the arrangement, in order to show that the wide tube is closed at the bottom like a test tube, and communicates by a side tube with the flask below. At the other side is an extremely ingenious syphon-arrangement, which is automatic, and also leads into the flask. The flasks used are conical in shape, and have the weights marked on the necks. They have necks of the same diameter, so that they all fit one cork. In using the apparatus for milks I proceed as follows. Approximately 10cc. of the milk are measured into a small tared basin of porcelain, and the weight noted. The milk is then evaporated on the steam bath, with frequent stirring, in order to render it granular, until, on being removed and cooled, the residue is semi-solid. The residue can then be easily detached from the basin by means of an ordinary joiner's gouge, and is transferred to a paper cup, made by pressing a circular filter over the end of a glass cylinder. The cup and contents are then placed in the Soxhlet tube, the basin, etc., being thoroughly rinsed with dry ether, which is added to the residue. Sufficient ether is poured in to reach within a short distance of the bend of the syphon tube; and some ether is also placed in the conical flask. The various connections are then made, and the water bath below the flask started. The ether in the flask distils up through the side tube into the wide one, containing the residue, and as soon as the surface reaches the bend of the syphon, it is at once carried over into the flask below, carrying the extracted fat along with it. This process is repeated over and over again. Provided the joints are all tight, the apparatus can be left to itself for a long time. From one and a-half to two hours are quite sufficient. The flask is finally taken off, attached to an ordinary small condenser by a cork of the same size, and the ether distilled off. Within the last year or so a complete revolution has taken place as regards the extraction of fat from milk, in the introduction of "Adams's" paper coils for drying the milk up. These coils, several of which I have on the table, are made by rolling up long strips of thick white blotting paper into a not too closely compressed coil, and tying round with a thread. The coils are treated with ether to remove traces of fat from the paper. A quantity of the milk is placed in a small beaker, and the weight noted. A coil is then placed in the beaker so as to be not more than half immersed, and allowed to remain till no more milk is drawn up. It is then removed, the dry end placed on a glass plate, and the whole kept for two hours in a closed water bath, after which it is transferred to the Soxhlet tube, and extracted in the usual way. I have been using these coils for some time (in conjunction with the older method) with excellent results, and have been able to confirm the fact—pointed out by the committee of the Society of Public Analysts—that from ·3 to ·5 per cent, more fat is extracted by this method. The process has also been recently examined by several German chemists, who have recommended its adoption there. I believe the coil method of drying up milk for fat extractions will quite take the place of all others. In the case of duplicates, the results are very concordant. In his book on Milk Analysis, etc., Dr. Bell, of Somerset House, states that he has obtained less fat when using the Soxhlet's tube than by his own marceration process. This is certainly not my experience. A great advantage also is that the apparatus being automatic, requires no attention, thus saving much time. It can also be used for many purposes of extraction, such as oil cakes, etc. I have also found it extremely convenient for determining grease in cloths to be used for waterproofing purposes, and in which the presence of any considerable quantity of fat is objectionable.

DISCUSSION.

Dr. WALLACE said that so far as he knew Dr. Milne was the first in Scotland who had made independent experiments upon this process of Adams's, as compared with the ordinary mode of extraction of fats; and it was very satisfactory to know that the results obtained agreed thoroughly with those of chemists in London and elsewhere. His own impression was that Soxhlet's apparatus was a very perfect one, so much so that he could not see why it should not extract every particle of fat in any substance. What, in his opinion, had prevented the general adoption of Adams's method was the fact that the Somerset House chemists had not yet taken it up. The same state of matters existed with regard to the standard of light. So far as legislation had yet gone, there was only one standard of light—*i.e.*, the sperm candle, which was a very imperfect standard, and yet people continued to use it, because no other standard was recognised. Public analysts were in the same position with regard to the analysis of milk and the extraction of fat. He hoped, therefore, that Dr. Bell, of Somerset House, would start independent experiments, and convince himself regarding the analysis of milk.

Mr. STANFORD said the Section was certainly indebted to Dr. Milne for the excellent apparatus, and the able manner in which he had brought his subject before them. He believed that one of the difficulties pointed out by Dr. Milne, in connection with the nesslerising tubes, might be obviated by making the bottom of white enamelled glass.

Mr. GALBRAITH suggested that instead of setting the Nessler tube on a white slab, a thin disc of porcelain might be dropped into the tube before use, as it would not then matter whether the glass at the foot of the tube was perfectly transparent or not.

At the close of the discussion on Dr. Milne's paper, Mr. C. M. AIKMAN, M.A., B.Sc., exhibited Bayne's new form of condensing apparatus for water analysis. The construction is simple, the condenser consisting of an oblong box of block tin, with a tube running through it, the water for cooling runs in at one end and out at the other end of the upper surface. The apparatus, Mr. Aikman said, combined several advantages over the older forms of condensers, not the least of which was the escape from the danger of breakage.

Nottingham Section.

Hon. Local Secretary:
J. R. Ashwell, Midanbury Lodge, Bentinck Road,
Nottingham.

At an early date, "Water Softening," by J. B. Coleman.

Notices of papers and communications for the meetings to be sent to the Local Secretary.

The Opening Meeting of the Session was held at University College, Nottingham, on November 19.

PROFESSOR CLOWES, D.SC., IN THE CHAIR.

The Chairman, in reviewing the work of the past session, stated that the inaugural soirée, held on June 5, 1885, had been followed by two lectures, to which the public were invited; Dr. Bowman, of Halifax, lecturing on "The Structure of Fibres used in Textile Fabrics," and Mr. T. Wardle, of Leek, selecting "Silk" for his subject. Both lectures were profusely illustrated, and well attended and received. At the ordinary meetings of the Society the following papers had been read and discussed:—"The Analysis of Gas Coal," by Lewis T. Wright; "Water Purification and Softening," by P. A. Maignen, "Use of Poisonous Materials in Dyeing Hosiery," by J. R. Ashwell and H. Forth: "Some Points in the Analysis of Oils," by L. Archbutt. The Publication Committee of the Society had acknowledged the importance of these papers by publishing all of them in the Journal. As regards papers for subsequent meetings, the Secretary had a goodly number of promises, but was quite open to receive more; and members were urged to fix dates, some of them *early* dates, for reading their papers. Members were reminded that communications were not necessarily composed of original work, or investigations carried out by their authors, although this would naturally be the highest standard to be kept in view. Accurate descriptions of processes not generally fully known to chemists, and furnished by men with special knowledge and experience of such processes, would usually be of value to the Section, and possibly even to the Society at large. Smaller shorter papers, constituting brief notes or notices, would also be welcomed, and might lead to useful discussion. The exhibition of chemical products, apparatus, or models likely to be interesting on account of their novelty, or from some other special characteristic, would also be welcome.

Meeting held Monday, December 13, 1886.

LIQUID FUEL.

BY LEWIS T. WRIGHT.

In 1883 I had the honour of addressing the Manchester Section of this Society on the subject of "Gaseous Fuel," a subject then of absorbing interest, and the theme for numerous "papers." The attention of the technical world now seems likely to turn to "Liquid Fuel," since we are threatened with a deluge of petroleum, which would no doubt be an accomplished fact if it were possible for this material to be delivered at such a price as to enable it to compete with our cheap English coals. The fine paper read before the London Section of this Society in 1885, "On the Russian Petroleum Industry," by Mr. Boverton Redwood, has given us an idea of the enormous quantities of petroleum seeking a market; but we have yet to learn the lowest price at which it can be delivered in this country, for on the price depends, of course, whether it can successfully compete with coals. Mr. Redwood states that at Nobel's works 1lb. of petroleum residue evaporated 14½lb. of water in a boiler provided with Nobel's trough burner, and 12lb. when injected into the furnace by steam, whereas coal was only equal to from 7lb. to 8lb. of water. It is probable that the coal employed was not of the finest quality. I do not know what the constitution of the petroleum residue may be—but the higher classes of petroleum are surely the most concentrated fuel, weight for weight, we can hope to find. Whilst the American petroleum oils are mostly hydrocarbons of the paraffin series, the Russian appear to be mostly pseudo-olefines (napthenes) and benzenoid hydrocarbons. You will remember that the hydrocarbons of the paraffin series up to heptane have positive heats of formation, and from the regular progression presented by those bodies, as far as they have been investigated, we may conclude that the higher members of the series also have positive heats of formation, and yield on combustion less heat than would be indicated by their elementary composition, or calculated according to Dulong's formula. Methane, the first member of the series, yields on combustion about 11 per cent. less heat than would be given by the same amount of carbon and hydrogen in the free state. Hexane about 6 per cent. less. The members of the olefine series, at present studied, have either negative heats of formation or very small positive ones. Of the acetylene series, the two first members, acetylene and ethylene, have negative, and diallyl (C_6H_{10}) a small positive heat of formation; naphthalene, anthracene and benzene appear to have negative heats of formation. I mention these matters as I think it probable that carbon for carbon and hydrogen for hydrogen, the Russian will be found to yield more heat than American petroleums. As engineers we labour under the difficulty of being compelled to employ an empirical formula for the calculation of the combustion equivalents of our fuels, and this difficulty can only be removed when the chemists have had time to determine for us the true calorific values of the materials we employ as fuel. Until then we shall have to avail ourselves of Dulong's formula, with the mental reservation that it is likely to give results perhaps 8 per cent. from the truth. It is well known that most coals at present investigated yield in the calorimeter higher results than are obtained by calculation. There are, however, exceptions. I find that fourteen coals examined by Scheurer-Kestner and Meunier in their calorimeter gave an average result 9 per cent. in excess of the average calculated value. The coals examined by Ferd. Fischer, in his boiler trials, also gave about 7 or 8 per cent. more in the calorimeter than calculated from elementary composition[*]. I have had no experience of petroleum as a fuel, but I venture to make a theoretical comparison between it and coal. The average composition of fifteen petroleums from various parts analysed by M. Sainte-Claire Deville was—

Carbon..............	81·7
Hydrogen	13·1
Oxygen	2·2
	100·0

which gives a theoretical evaporative power per lb. of 19·63lb. water from a temperature of 100° C. at atmospheric pressure, reckoning the H_2O formed on combustion of the hydrogen to be in the gaseous condition, thus:—

$$\frac{84{\cdot}7\times8080+\left(13{\cdot}1-\frac{2{\cdot}2}{8}\right)28780}{536{\cdot}5\times100}=19{\cdot}63.$$

(the theoretical evaporative power will always be expressed on this basis). In a good boiler we may

---

[*] Wagner's Jahresbericht, 1883—1885.

expect to get 80 per cent. of the calculated heat of combustion of such a class of fuel into the water. We should then have an actual evaporative power of 15·70lb. water; but as about 5 per cent. of the water evaporated would be required to work the injector, if the petroleum were worked on that system, we should have a net evaporative power of 14·92lb water. This estimate gives petroleum weight for weight 32 per cent. more evaporative power than coal of a practical evaporative power of 11·3lb.

D. K. Clark, in his "Manual of Rules and Tables," falls into a singular error in his notes on "Liquid Fuels," and credits some petroleum oils with a theoretical evaporative power of 29·08lb. A glance at the formulæ and elementary composition of his petroleum oils will immediately cause the error to be disclosed. In his otherwise useful manual the custom of calculating the combustion values of the fuels on the basis of the H_2O formed on combustion of the fuel being liquid, is objectionable, as it operates unfairly against those fuels containing but little hydrogen, and is a condition not to be arrived at in practice.

No doubt some of the purer petroleum distillates might give one or two pounds more than this figure, but would they not be commensurately dearer !

A crude petroleum of ·87 specific gravity would measure 257½ gallons to the ton of 2240lb., and at one penny per gallon would be equivalent to a coal of the above mentioned quality at 16s. 3d. per ton, without reckoning anything on account of a saving in labour of firing, and other advantages liquid fuel possesses, such as getting more work out of the boiler, etc. It is impossible to assign any value to these, as everything would depend upon particular circumstances. Of course, if it were found that trough burners could be successfully employed, then the comparison would be much more favourable to the petroleum; but petroleum at one penny per gallon is, at present, a thing only to be dreamt of. There are other liquid or semi-liquid fuels produced in this country at a very low price, such as tar oils and tar, and the attention of engineers and manufacturers who require *intense* and *regular* heats should be directed to these. The results of the boiler trials I have made with tar and creosote, and which were casually mentioned in a paper I read before the London Section of this Society, on November 1 last, I now propose to bring before your notice. The results in the paper referred to were given for actual working conditions—viz., feed water at 12° C. (53·6° F.) and 40lb. steam pressure. The boiler was a two-flued Galloway boiler 28ft. long, 7ft. diameter, of the best modern construction:—

Class of Fuel.	Number of Days Trial.	Pounds of Water evaporated from 12° C. at 40lb. Steam Pressure.	Pounds of Water from 100° C. and Atmospheric Pressure.
Nottingham Top Hard Cannel	11	7·40	8·78
Silkstone Gas Coal	7	8·42	10·01
Coke from Top Hard Cannel	6	8·31	9·91
Silkstone Gas Coke	6	9·49	11·15
Tar Steam injected	7	10·70	12·71
Creosote Steam injected	9	11·24	13·35

I give coals and coke in this table for the purpose of comparison.

I will now give the elementary composition of the materials employed, and their calorific values calculated according to the usual formula:—

$$\frac{C \times 8080 + \left(H - \frac{O}{8}\right)28780 - (H_2O \times 600)}{536{\cdot}5 \times 100.}$$

The carbon, hydrogen, oxygen, and moisture, etc., being expressed per cent., and the result being in units (lbs.) by weight of water evaporated from 100° C., and atmospheric pressure per unit (lbs.) weight of fuel.

The *Nottinghamshire top hard cannel* employed has the following elementary composition:—

C	67·0
H	5·6
N	1·2
S	1·0
H_2O	7·6
Ash	6·6
O	11·0
	100·0

$$\frac{67 \times 8080 + 28780\left(5{\cdot}6 - \frac{11{\cdot}0}{8}\right) - (7{\cdot}6 \times 600)}{536{\cdot}5 \times 100} = 12{\cdot}27$$

and would therefore have a theoretical evaporative power of 12·27lb. of water per 1lb. of fuel.

The Silkstone Coal—

C	79·0
H	5·2
N	1·5
S	1·5
H_2O	4·0
Ash	2·8
O	6·0
	100·0

$$\frac{79 \times 8080 + 28780\left(5{\cdot}2 - \frac{6{\cdot}0}{8}\right) - (4 \times 600)}{536{\cdot}5 \times 100} = 14{\cdot}24$$

with a theoretical evaporative power of 14·24lb. water per 1lb. of fuel.

The Top Hard Cannel Coke—

C	80·1
H	0·6
N	1·3
S	0·4
H_2O	4·1
Ash	11·9
O	1·6
	100·0

$$\frac{80{\cdot}1 \times 8080 + 28780\left(0{\cdot}6 - \frac{1{\cdot}6}{8}\right) - (4{\cdot}1 \times 600)}{536{\cdot}5 \times 100} = 12{\cdot}23$$

with a theoretical evaporative power of 12·23lb. of water per 1lb. of fuel.

The Silkstone Gas Coke—

C	89·0
H	1·0
N	1·0
S	1·2
H_2O	1·2
Ash	5·2
O	1·4
	100·0

$$\frac{8080 \times 89 + \left(1{\cdot}0 - \frac{1{\cdot}4}{8}\right)28780 - (1{\cdot}2 \times 600)}{536{\cdot}5 \times 100} = 13{\cdot}83$$

with a theoretical evaporative power of 13·83lb. of water.

The Tar—

C	80·2
H	7·0
N	0·8
S	0·5
O	11·5
	100·0

$$\frac{8080 \times 80{\cdot}2 + \left(7{\cdot} - \frac{11{\cdot}5}{8}\right)28780}{536{\cdot}5 \times 100} = 15{\cdot}06$$

with a theoretical evaporative power of 15·06lb. of water.

The Creosote—

C	87·4
H	7·3
N	0·3
S	0·5
O	4·5
	100·0

$$\frac{8080 \times 87\cdot4 + \left(7\cdot3 - \frac{4\cdot5}{8}\right)28780}{536\cdot5 \times 100} = 16\cdot78$$

with a theoretical evaporative power of 16·78lb. of water.

The following table gives the percentage of the theoretical evaporative power actually obtained:—

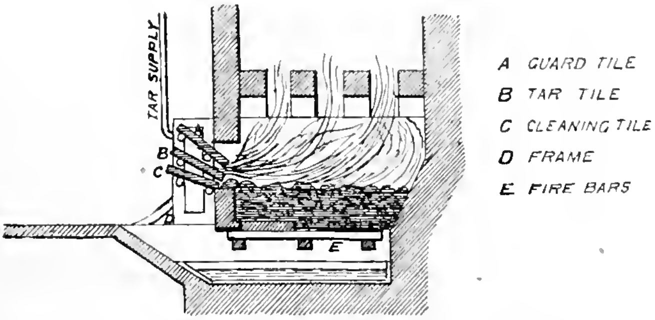
	Actual.	Calculated.	Per Cent.
Nottingham T. H. Cannel	8·78	12·27	71·56
Yorkshire Silkstone Coal	10·01	14·21	70·30
T. H. Cannel Coke	9·91	12·23	81·03
Silkstone Gas Coke	11·15	13·83	80·62
Tar Steam Injected	12·71	15·06	84·40
Creosote ,, ...	13·35	16·78	79·56

It will be observed that the coals come out low, the cokes and tar very well, and the creosote occupies a mediate position. It is also important to bear in mind that the coals examined by Scheurer-Kestner and Fischer were really seven to nine per cent. better than by calculation; but I cannot say that this would also apply to the coals used. The creosote results agree fairly with some I have had the privilege of seeing, that were obtained in the London district, and also in the neighbourhood of Nottingham; but as I have no information about the boilers employed, a close comparison is not possible. Creosote is an excellent fuel for boiler firing, and easy to manipulate. It requires to be warmed if it contains much "tar salts," to dissolve the naphthalene, etc. Tar is rather more difficult to manage with ordinary forms of injectors, as the peculiar orifices employed are extremely liable to obstruction with this viscous fluid, and there is a tendency to produce smoke if the flow of tar is irregular.

For the purpose of injecting these liquid fuels into furnaces, a great number of injectors have been invented, and if they materially differed in principle the study of them would be perfectly bewildering, but as they are almost all alike their study is really very simple. The one on the table before you is perhaps the simplest form, and is one I designed, and have called a "spray burner," and consists of one tube carrying the steam placed at right angles to another carrying the liquid fuel, in the fashion of those scent sprays that were and are, perhaps, now very popular for distributing scent in rooms.

These injectors are said to require about five per cent. of the steam made to work them, and suffer from the obvious difficulty of not being able to raise the steam to start themselves with. A supplementary boiler, fired by other means, would have to provide that in the first instance. There is no doubt that the oil could be burned without steam at all, after the manner of Nobel's trough burner. I have tried with an arrangement similar to the one I shall shortly describe for retort furnaces; but it was not large enough to be able to consume enough oil to evaporate anything like the usual quantity of water. Up to that point, however, the combustion of fuel was very perfect, and gave great promise for an extension of the system. The flame from these oils is very fierce, and it is no doubt advisable to place a ring of fire-bricks as a lining for those parts of the boiler in immediate vicinity to the flame, and fire-brick shields in front of the first tubes, if the boiler is of a Galloway type. The grate also wants covering with either a dense bed of ashes or fire tiles, and the lower half of the flue below the grate should be closed with a metal shield. I am inclined to think that it would be preferable, if the use of oil were intended to be permanent, to employ a fire-box of firebrick outside the boiler, with a furnace of the type to be described hereafter, and lead the flame into the boiler flues.

The attention of gas engineers has been forcibly directed to the use of tar as a fuel for the firing of retorts, now that this once high-priced material is suffering like everything else, perhaps even to a more marked extent, from what is called depression in trade, it has in many places reached so low a commercial value that it is profitable to burn it as a fuel. Happily, at Nottingham this is not the case, and our interest in tar as a fuel is more experimental in view of what may happen if a further fall in tar products sets in. I have abandoned the use of steam injection for our experimental tar fires, in favour of another system I am going to describe. The steam injectors produce magnificent heats, but are rather intermittent in their action, and the steam they require is a serious item and not always available.



Tar being a pseudo-liquid fuel, in arranging for its combustion one has to provide for the twenty to twenty-five per cent. of solid carbon it contains, and that is deposited in the furnace as a kind of coke or breeze on the distillation of the volatile portions, which are much more easily consumed than the tar-coke. The tar fire I have adopted is one that can readily be adapted to an ordinary coke furnace, and as readily removed, leaving the furnace as before. The accompanying sketch shows the arrangement.

An iron frame D standing on legs on the floor just in front of the furnace-door carries three fire-tiles on iron bearers. The upper one A is not moved, and serves to shield the upper face of the tile B from the fierce heat radiated from the furnace, and also causes the air that rushes into the furnace between the tiles A and B to travel over the upper face of the tile B on which the tar flows, thereby keeping it cool and preventing the tar from bursting into flame until it reaches the edge of the tile B, over the whole edge of which it is made to run fairly well by a distributing arrangement. A rapid combustion takes place here, but some unconsumed tar falls on to the bed below. About one-third of the grate area is filled up by a fire-tile, and on this the tar coke falls. The tile C is moved away from time to time, and the tar-coke that accumulates in front of it is pushed back on to the fire-bars E, at the back of the furnace, to be there consumed. Air is thus admitted by three narrow slot-like openings to the front of the furnace between the tiles A, B and C and under C and through the fire-bars E. The air openings below are about three times the area of the openings in the front of the furnace, but as the openings between the fire-bars and tiles are always more or less covered by tar-coke, it is impossible to say what the effective openings are. The disposition above described is found to answer admirably, and requires but little attention. Three minutes per hour per fire seems to be the average time required for attention, and the labour is of a very light kind, and consists of clearing the passages between the tiles, and occasionally pushing back the coke on to the fire-bars. These latter are not interfered with, and will not require cleaning unless any bricks in the furnace have been melted, when a bed of slag will be found on them.

The amount of draught required for these fires is very small, and less than with coke firing. I find that 0·08 of an inch vacuum is sufficient with tar fires, and 0·25 of an inch for coke fires. The fires would require less attention with more draught, and more tar, as the apertures do not easily close with a sharp draught, and the tar is better carried forward into the furnace. A regular feed of tar is, of course, required, and considerable difficulty seems to be experienced in obtaining this. So long as we employed ordinary forms of taps or valves, so long (even with filtration) did I experience difficulties with the flow of the viscous tar, but on the construction of valves specially designed for the regulation of its flow, this difficulty immediately disappeared, and there is no longer the slighest trouble on this account.

The labour connected with the feeding of furnaces with coke, and cleaning fires from clinker, is very arduous. Eight coke fires are normally considered to be work for one man. A lad could work 16 of these fires.

Considerable attention has been paid to the composition of the furnace gases from the tar fires. The slightest deficiency in the air supply, of course, results in the immediate production of smoke, so that the damper must be set to provide always a sufficient air supply. Under these circumstances of damper the following analyses have been obtained :—

Obituary

SIR FRANCIS BOLTON.

Sir Francis Bolton died on 5th January at the Royal Bath Hotel, Bournemouth, where he and Lady Bolton had been staying for the last two months.

The deceased was born in 1831, and, entering the Army in 1857, was staff officer on the Gold Coast from 1858 to 1860. He became captain of the 12th Foot in 1861, major (unattached) for special military scientific services in 1868, lieut.-colonel in 1877, and retired colonel in 1881. He was the inventor of the system of telegraphy and visual signalling introduced into Her Majesty's Service in 1863. Since 1871 he had been the water examiner under the Board of Trade; and was the founder, vice-president, and hon. secretary of the Society of Electricians. Sir Francis Bolton will be best recollected by the general public in connection with the Health, Inventions, and Colonial and Indian Exhibitions, in all of which he played an important part. It was entirely due to the invention of Sir Francis that the prismatic fountains, which formed such an attraction at these exhibitions, were introduced, and it was under his immediate supervision that they were installed and improved. The Colonel was an implicit believer in his invention, and continued improving and enlarging on it up to the time of his death. The manipulating of the electric signals by means of which the fountains were worked was rarely entrusted to anyone by the inventor, and six nights out of seven it was Sir Francis himself who directed the operations from the little room in the clock tower. It was his great delight to be surrounded by ladies and gentlemen of his acquaintance, to whom he loved to exhibit the working of the machinery, and he was generally accompanied by a small circle of friends on his visits to the tower. Sir Francis had for a long time past been an acute sufferer, the symptoms of his disease which gave most trouble being an almost total loss of voice. In the hope of improving his condition, he underwent several operations, but with little result, and experienced considerable pain, notwithstanding which he invariably appeared in the best of spirits, and frequently made jokes at his own expense in reference to his loss of voice. Sir Francis was in appearance of somewhat burly build, and had a fine presence. He was exceedingly popular with all who came in contact with him, and his bearing towards his employés, even of the lower grades, was such as to render him exceedingly popular with them also.

Journal and Patent* Literature.

I.—GENERAL PLANT, APPARATUS, AND MACHINERY.

Improvements relating to Filtration and Apparatus therefor. H. Stockheim, Mannheim, Germany. Eng. Pat. 397, Jan. 9, 1886. 8d.

THE specification describes a closed filter casing which is separated into two compartments by a division plate, and fitted with connecting pipes by means of which the compartments can be used either together or separately, in the latter case capable of treating different liquids if required. The invention next refers to a new filtering medium composed of two parts of dry, white, ground wood fibre, and one part of dry linen fibre, successively treated with soda lye, bisulphite of lime, and a small quantity of sulphuric acid, under repeated boilings and washings. After exposing for a day or two, boiling in steam and washing in cold water, it is finally treated with alcohol free from fusel oil for the purpose of preservation.—B.

An Improved Compound for Preventing and Removing Incrustation in Steam Boilers. J. L. Wade, Glasgow. Eng. Pat. 1037, Jan. 23, 1886. 6d.

THE inventor prepares the following compound—viz., 40 parts of esparto grass boiled in water to a pulp, to which are added 20 parts of powdered nut galls, and 20 parts of chestnut pitch extract. The mixture is boiled to homogeneity, when the following substances are added in solution—viz., carbonate of potash, chloride of potash, and silicate of soda 10 parts each, and of chestnut flour 20 parts. The quantity and composition is varied with the composition of the water to be treated, and he sometimes adds valonia and glycerine, the latter in 2½ times the quantity of the former. The mass on cooling may either solidify or remain fluid or semi-fluid, according to ingredients used, and is applied accordingly.—B.

Improvements in Raising Liquids and in Apparatus therefor. J. Mactear. From J. Kolb, Lille, France. Eng. Pat. 1990, Feb. 11, 1886. 8d.

THE invention is based on the principle that if two columns of liquid balance each other, one may be made of less specific gravity taken as a whole than the other, by intimately mixing with it air or gases in a state of minute subdivision. Application of this principle may for instance be made to a syphon in the way of drawing the liquid from a lower reservoir up through the long leg, and delivering it by means of the short leg into a higher reservoir. Air finely divided being admitted near the lower end of the long leg of the syphon, at the same time that exhausting action is applied at the highest points, the liquid will rise and be discharged as described. Other applications are shown in the specification.—B.

Improvements in Apparatus for the Manufacture of Acids and Distillation and Condensation of Corrosive Liquid and Gaseous Substances. J. Whitley, Leeds. Eng. Pat. 10,022, Aug. 5, 1886. 4d.

THIS refers only to the substitution of aluminium, or aluminium bronzes consisting of copper with from 10 to 50 per cent. of aluminium, for lead or brass in the manufacture of articles used in connection with apparatus as referred to in the title.—B.

Improvement in Vacuum Distillation Apparatus. H. T. Yaryan, Toledo, Ohio, U.S.A. Eng. Pat. 14,162, Nov. 3, 1886. 8d.

THE apparatus consists essentially of double coils of piping arranged one within the other and fitted in a special way, the inner pipe containing the liquid to be evaporated and the surrounding one the heating medium, such as steam. If several coils are used successively for double and triple effect, the steam coming off the liquid evaporated in the first inner coil may be used for heating the next coil or coils. The remainder of the apparatus is principally required for regulating the proper supply, distribution, and direction of flow of the liquids and vapours. A modification of the apparatus is also proposed in the substitution of multitubular evaporators for the double coils previously named. For further details the specification and its two sheets of drawings must be consulted. The number of claims set up is 27. —B.

II.—FUEL, GAS, AND LIGHT.

The Examination of Petroleum.† C. Engler. Chem. Zeit. 10, 1335.

IN referring to experiments by Chandler, R. Weber, and the Berlin officer of health, on the heating of the lamp reservoir in petroleum lamps, the author comes to the same conclusion as V. Meyer—viz., that the use of lamps should be forbidden in which the oil is heated to more than 5° C. above the surrounding temperature. A criticism on Thoerner's conclusions on the value and examination of petroleum (this Journal, 1886, 371) is entered into, with which the author in the main agrees. He admits the safety of an oil the flashing point of which is above 38°, but considers that, taking the expense of the oil and other matters into account, the raising of the minimum flashing point from 21° to 23° would be sufficient. That the temperature of ignition of oils in the oil reservoir of a lamp, or when determined by Abel's apparatus, only show slight differences as stated by Thoerner, both his own experiments, as well as those of R. Weber and of the Berlin officer of health disprove, differences of 7—10° having been observed on an average. This difference is chiefly due to the relation existing between the empty space in the reservoir and that occupied by the oil. An Abel's apparatus filled with 30cc. of various oils gave flashing points from 4° to 11°·5 above those obtained when the apparatus contained 75cc. (the normal amount) of these oils. The greater the relative volume of air, both in Abel's apparatus and in lamp reservoirs, the higher appears to be the flashing point. The harmless nature of the explosions in oil lamp reservoirs, as commented upon by Thoerner, has been thoroughly investigated by Weber, who has determined the exact conditions under which the explosions may be either of a violent or of a mild nature. No appreciable change appears to take place in the composition of an oil before and after the burning of a portion. This confirms Thoerner's results. The diminution in the illuminating power of a lamp after it has burned for some hours is due, as Thoerner found, to (1) the deposition of carbon on the wick, and (2) the greater distance through which the oil has to rise as its consumption continues. The former is the prime cause, and is diminished to varying extents by an increased supply of air. This diminution of the illuminating power of a lamp increases with the amount of heavy oils present. The rate of rise of an oil in the wick is independent of its specific gravity, except for different portions of one and the same kind of oil. It is directly dependent upon the viscosity of the oil. The author then remarks on the necessity of testing the illuminating power of oils by means of those lamps best suited for them, and *vice versa* in testing different forms of lamps to use those oils for which they are most applicable.—C. A. K.

III.—DESTRUCTIVE DISTILLATION, TAR PRODUCTS, Etc.

Notes from Baku. Chem. Zeit. **10**, 1337.

ALTHOUGH large quantities of petroleum are still obtained from the Baku region, it appears nevertheless that the yield is steadily decreasing, and that in four or five years it will hardly suffice to supply the Russian demand alone. Borings are now made to depths of 100—150 fathoms where formerly the oil was reached at 40—45 fathoms. In some cases borings right through the oil containing strata on to the underlying volcanic rocks (300 fathoms) have failed to produce oil. Boring is nevertheless continued, although the price of oil, owing to the market being overstocked, is practically nothing. The price for crude naphtha on the spot is less than a half-penny per gallon, and for petroleum and kerosine of the best quality 2d. per gallon. The opening up of new localities for boring is contemplated, and the whole district between the greater and lesser Caucasus is believed to contain oil-yielding strata. The value of the Baku products could be considerably enhanced were capital and chemical knowledge at hand to effect improvements in the processes employed.
—C. A. K.

IV.—COLOURING MATTERS AND DYES.

Preparation of Ultramarine Blue in the Wet Way. F. Knapp. J. Prakt. Chem. **34**, 328—340.

IN a previous communication (this Journal, 1886, 238, and *J. Prakt. Chem.* **32**, 375) the author referred to the uncertainty of converting the ultramarine mixture into the blue product in the wet way, and expressed the opinion that the formation of the blue is dependent on conditions which are as yet unknown. On fusing, the ultramarine mixture assumes a yellow colour, which subsequently changes to a brown tone, indicative of the completion of the fusion process. These conditions are entirely altered if air is allowed to have access to the mixture, the brown colour of the product being again changed to a yellow shade, which cannot be distinguished from the original colour, so that it is difficult to determine the end of the operation.

The author has obtained a species of ultramarine blue in the wet way from silica (without alumina). The success of the preparation, however, depends on the nature and condition of the silica employed. The results obtained with finely pulverised quartz being unsatisfactory, the silica was used in the form of a gelatinous precipitate. For this purpose a solution of sodium silicate was treated with an acid, the washed precipitate mixed with sodium carbonate and sulphur, then dried and heated. The yellowish-grey product, when moistened with water or with "liver of sulphur" solution, gradually became blue, but the colour was not very permanent. Better results were obtained when the following method was used:—A weighed quantity of commercial soda water glass (containing one third of its weight of solid sodium silicate) was treated with seven parts of water and the theoretical amount of hydrochloric acid required to precipitate the silica. Owing to the dilution of the liquid the silica remained in solution together with the sodium chloride. The mixture was then treated with sulphur and sodium carbonate in equivalent proportions to the amount of silica contained in the solution. It is recommended to moisten the sulphur with alcohol before it is added to the solution, owing to the difficulty experienced in mixing it with the other ingredients. The mixture was then dried and heated for about forty minutes at a dull red heat. A yellowish-grey mass was obtained which gave the deep blue of ultramarine on digestion with a solution of "liver of sulphur." The product was, however, more soluble in water than the blue obtained with a mixture of kaolin, soda, and sulphur.

Alumina yields a species of ultramarine blue which closely resembles the product prepared from silica. The behaviour of alumina in the presence of sodium carbonate and sulphur is, however, essentially different. On heating a mixture containing equal parts of alumina (in a gelatinous form), sulphur and sodium carbonate, sulphur is freely expelled and a white mass obtained, which consists mainly of sodium aluminate. The opposite result is obtained when the alumina is converted into the aluminate before it is mixed and fused with sulphur and sodium carbonate. Whilst on saturating a solution of soda with alumina in the cold, three atoms of Na_2O are taken up, only one atom is fixed when the mixture is heated to redness.

In conclusion it is stated that common salt may be permanently tinged blue with sulphur alone. It is also shown that it is possible to obtain a colour resembling ultramarine blue from substances having no direct bearing on the chemical constitution of ultramarine. Thus on heating a mixture of calcium phosphate, sodium carbonate and sulphur, a good medium blue is obtained. It is a remarkable coincidence that on mixing tricalcium phosphate with a concentrated solution of freshly ignited "liver of sulphur," the mixture gradually assumes a blue colour in the cold.—D. B.

V.—TEXTILES: COTTON, WOOL, SILK, Etc.

Vegetable Silk from Cameroons. Chem. Zeit. **10**, 1335.

THE seeds of a species of *Cochlospermum* are surrounded with a covering of fine hairs, which are, however, too brittle and too loosely attached to render them of any importance for weaving purposes, even if mixed with other fibres. This is also the case with the hairs found on the seeds of several other plants (*Chem. Zeit.* **7**, 406). It is suggested that these hairs might be made use of in stuffing cushions, etc., or in twine making. These fibres are coloured faint red by phloroglucinol and hydrochloric acid, with aniline sulphate faint yellow, and are, accordingly, slightly lignified. The colour of a considerable portion of the fibres is somewhat yellowish, the lustre not insignificant (see this Journal, 1886, 642).
—C. A. K.

Improvements in the Treatment of Animal Fibres or Mixed Fabrics to remove Vegetable Matters therefrom. O. Chemin. Eng. Pat. 564, Jan. 13, 1886. 6d.

THE inventor substitutes hydrofluoric acid for the hydrochloric acid gas employed by other inventors.—E. J. B.

VII.—ACIDS, ALKALIS, AND SALTS.

Ignatjewite, a new variety of Aluminite. K. Flug. Chem. Zeit. **10**, 1291.

SPECIMENS examined obtained from Bachmut (Ekaterinoslaw, Russia), in the form of colourless kidney-shaped concretions, resembling kaolin or chalk in appearance. An analysis given shows the presence of 36·39 per cent. total Al_2O_3, more than half of which appears to be present as hydrate. The importance of this mineral for the preparation of aluminium sulphate and alum is remarked upon by the author.—C. A. K.

Eubœan Magnesite. A. Christomanus. Chem. Zeit. **10**, 1337.

A VERY pure magnesite, containing, according to analysis, 94·46 per cent. $MgCO_3$. The deposits are large, but localised.—C. A. K.

Notes from Baku. Chem. Zeit. **10**, 1337.

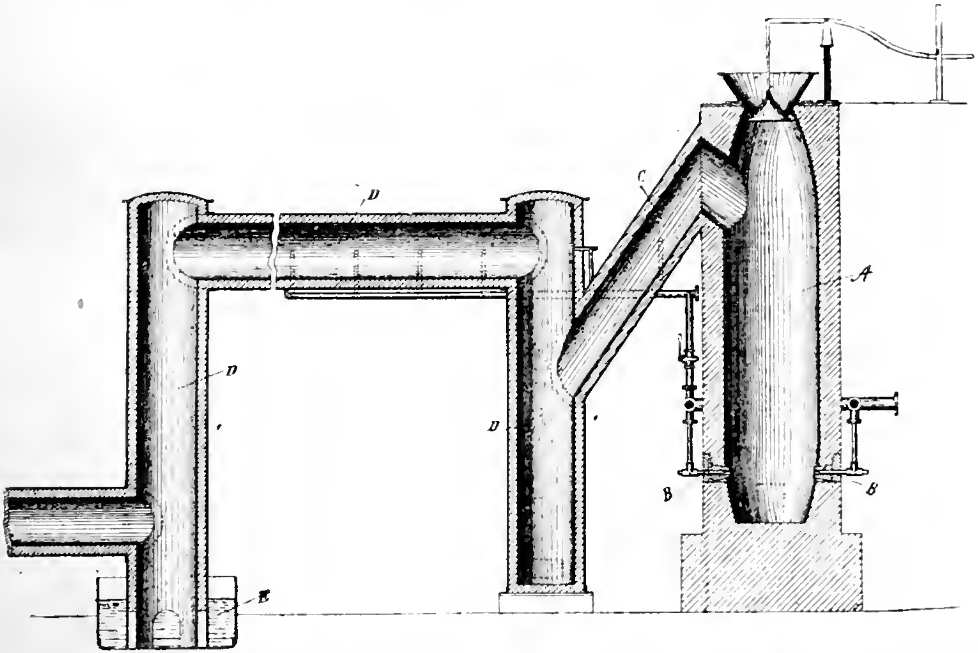
THE manganese ores obtained from this district (Kwirilskaja, Beschatuban, and Tiflis) are so plentiful that only the good and large pieces are considered worth the transport. The competition is very keen, the ore being almost wholly exported to England and France.
—C. A. K.

Improvements in the Manufacture of Alum and Sulphate of Alumina. T. Robinson, Glasgow. Eng. Pat. 150, Jan. 5, 1886. 6d.

The calcined alum yielding material is treated with sulphuric acid in the usual manner for obtaining a solution of aluminium sulphate. Sufficient calcium sulphide, in the form of Leblanc vat waste, is then added to neutralise any free acid and precipitate arsenic and other impurities. The "yellow liquor" from the vat waste may be substituted for solid calcium sulphide. —S. H.

An Improved Process for the Production of Sulphurous Acid Gas. John and James Addie, Langloan, N.B. Eng. Pat. 180, Jan. 5, 1886. 8d.

This invention consists of a process for the production of sulphur dioxide from pyrites or other sulphur compounds, wherein the sulphur, in combination with a metal, is replaced by silica, or other slag-producing material, and being thus liberated, is oxidised by a blast of hot or cold air. A small blast-furnace or cupola A is heated to a white heat, and then charged with a mixture of pyrites and sandstone, siliceous limestone, or other slag-producing material. A hot blast is directed into the furnace through the tuyères B, by which the mixture is reduced to the molten state, the sulphur being set free and carried upwards, together with some sulphurous acid formed, while the silica, combining with the iron, forms a slag, which is run off from time to time. In the upper part of the furnace, which is closed with a hopper-charging arrangement, or into the brick-lined tubes C and D, a blast of hot or cold air is directed, in order to completely burn the sulphur, which rises in a finely-divided state from the heated materials below. In connection with the pipe D, is a water lute E, which serves as a safety valve in the event of excessive pressure of the gas.—S. H.



Improvements in the Manufacture of Bicarbonate of Soda and Soda-Ash. N. Mathieson and J. Hawliczek, Widnes. Eng. Pat. 227, Jan. 6, 1886. 6d.

This invention has for its object the manufacture of either pure bicarbonate or of pure monocarbonate of soda direct from the crude "vat-liquor," or "red liquor," or "black ash," all of the Leblanc process, or from a solution of crude sodium sulphide, or from the crude sodium bicarbonate of the ammonia-soda process. If to a solution of chlorides or sulphates of an alkali there be added a solution of crude sodium carbonate, and the mixture be submitted to the action of carbonic acid gas, pure sodium bicarbonate is precipitated in a crystalline form. In practice vat-liquor is mixed with a strong solution of sodium chloride, or the black ash is directly lixiviated with brine and the mixture, obtained in either way, treated with carbonic acid. This treatment resolves itself into two stages—viz., the purifying and the carbonating process. In the first instance, the carbonic acid acts first on the crude liquors by precipitating alumina, iron, and silica. The solution is then filtered, and the clear liquor subjected to the further action of a current of carbonic acid gas, when pure sodium bicarbonate is precipitated. At this second stage, the sulphides and cyanides present are also decomposed, with the evolution of sulphuretted hydrogen and cyanogen. After washing, the bicarbonate is nearly chemically pure, and is either by drying converted into marketable sodium bicarbonate, or by calcining into pure monocarbonate. The liquor remaining consists mainly of sodium chloride, and can be used over and over again for lixiviating fresh black ash. To make pure bicarbonate from crude sodium bicarbonate (from the ammonia-soda process), the latter is dissolved in a solution of sodium chloride or sulphate, and subjected to the action of carbonic acid, whereby pure bicarbonate is precipitated. If a crude sodium sulphide solution be treated with carbonic acid in the manner previously mentioned, sodium bicarbonate is precipitated and sulphuretted hydrogen is evolved.—S. H.

Improvements in the Manufacture of Carbonates or Bicarbonates of Sodium or Potassium from their Sulphates. W. Bramley, Middlesbro'-on-Tees. Eng. Pat. 1050, Jan. 23, 1886. 6d.

Barium sulphate is reduced with coal to sulphide, and the latter treated with an excess of hydrochloric acid, so as to form barium chloride. To this solution magnesia, hydrate of magnesia, or hydrated magnesium carbonate is added, and carbonic acid, preferably under pressure, injected into it. The mixture is then heated and agitated in order to complete the reaction and drive off the excess of carbonic acid. Barium carbonate is thus precipitated, magnesium chloride being in solution. This solution is separated from the precipitate and treated for the recovery of the magnesia for further use and the production of chlorine and hydrochloric acid. The barium carbonate, after washing, is treated with a solution of sodium sulphate, or potassium sulphate, and carbonic acid gas is injected. Sodium or potassium bicarbonate is formed in solution and barium sulphate precipitated. For the decomposition of the bicarbonate and formation of sodium or potassium carbonate, magnesia is added to the solution in a closed vessel which is heated and agitated. The magnesia is rapidly converted into hydrated magnesium carbonate, which should be employed as previously described. The barium sulphate, after washing, also re-enters the cycle of operations.—S. H.

Improvements in Preparing Soda for Sale and Distribution. J. Mactear, London. Eng. Pat. 1989, Feb. 11, 1886. 4d.

Monohydrated or decahydrated sodium carbonate in a granulated state is compressed in suitable moulds so as to form tablets, cakes, or blocks of convenient size and weight. The most convenient shape is the rectangular form, allowing a number to be packed together without waste of space. The moulds may be arranged to impress a trade-mark on the blocks.—S. H.

Improvements in Apparatus for Distilling Ammoniacal Liquor for the Purpose of Producing Sulphate of Ammonia. A. Dempster, Yorkshire. Eng. Pat. 3220, March 8, 1886. 8d.

See this Journal, 1886, 379—381. This is an amended specification, made by merely deleting the fifth claim in the former specification, *loc. cit.*—W. S.

Producing Hyposulphite of Soda (Sodium Thiosulphate). T. Raynaud, Namur, Belgium. Eng. Pat. 12,255, Sept. 27, 1886. 6d.

Sodium hyposulphite is obtained by the action of sulphur dioxide on sodium sulphide, thus: $2Na_2S + 3SO_2 = S + 2Na_2S_2O_3$. The sodium sulphide solution required for this purpose is produced by the reduction of sodium sulphate with coal. This mass contains besides sodium monosulphide, the polysulphides, carbonate, hydrate, and sulphate of soda, together with hyposulphite of sodium (thiosulphate). The former by-products are not converted by sulphur dioxide into sodium hyposulphite, thereby forming a troublesome impurity in the solution during the process, and causing a loss of soda. The invention has for its object the treatment of the crude solution of sodium sulphide in such a manner that all the various compounds, except the sulphate, are converted by sulphurous acid into hyposulphite. This is effected by the addition of lime and sulphur, the former causticising the sodium carbonate, which is then acted upon by the sulphur, forming sodium sulphide.—S. H.

IX.—BUILDING MATERIALS, CLAYS, MORTARS, AND CEMENTS.

On the Causes of the Weathering of Building Stones. T. Egleston. Dingl. Polyt. J. **262**, 190—191.

The results of Professor Egleston's researches are communicated in a paper read before the American Society of Civil Engineers. He finds that under favourable climatic conditions granite is practically unaffected. But the influence of unfavourable conditions is evidenced by the present state of the Egyptian Obelisk in the Central Park of New York, which, after 2000 years exposure to the dry climate of Egypt, was yet free from deterioration, whilst only five years in New York has sufficed to bring about a rapid decay. Sandstones vary in their weather-resisting power according to their binding medium, those containing a siliceous medium being the most stable, those with lime, oxide of iron or organic matter being less so in order of sequence. Of limestones, pure calcium carbonate and pure dolomite are best. In mixtures of the two there is a fear of disintegration by the solution of the calcium carbonate from among the particles of dolomite. The greater degree of weathering observed in blocks close to the surface of the earth in large towns is due to the impregnation of these portions by water rising from below, and thrown upon them by water courses from above, since the damp stones are more affected by the acid atmosphere near the ground than they would be when dry. Moreover, at greater elevations the deleterious effects of the acid constituents are minimised by dilution with much free air. The author finds also that the wind laden with dust (mainly consisting of sharp sand particles) beating against the buildings causes a gradual surface wear. No stone, however hard (not even the diamond), was found capable of resisting the action of the sand blast, though but for a short time. He has observed, also, that in cemeteries the letters graven on the tombstones are frequently illegible where they are exposed to the prevailing wind of the place. Finally, Egleston emphasises the necessity for extreme care in the selection of building-stones, and in the arrangement of cornices and water ducts in such manner that the water may not fall or collect largely upon any portion of the stone work.

—W. G. M.

An Improved Cement or Composition for Various Purposes. J. Bidwell and A. Bidwell, Axminster. Eng. Pat. 517, Jan. 13, 1886. 6d.

To produce a cement which, when dry, will burnish to a bright gold or silver colour, the patentees mix white coburg, copal, mastic, and white hard varnish with zinc white, bisulphide of tin, and powdered Dutch foil; or when a silvery lustre is required the Dutch foil is replaced by silver powder.—C. C. H.

X.—METALLURGY, Etc.

On the Blue-shortness of Iron and Steel. Professor A. Ledebur. Dingl. Polyt. J. **262**, 166—169; and Glaser's Ann. 1886, 208.

For the sake of uniformity in nomenclature, the author proposes to term "blue-shortness" that sudden increase in the brittleness of iron occurring at the temperature (250—350°) at which the metal assumes a blue colour. Whilst red- and cold-shortness may be ascribed to the presence of certain well-known substances, blue-shortness, though doubtless increased by certain kinds of foreign matter, appears to be common to all varieties of iron and steel, but chiefly, it would seem, to the latter. Valton (*Berg. u. Hutt. Zeit.* 1877, 25) was the first to observe this phenomenon, and Huston, Walrand, and others have continued the investigations. From these it would appear that at the temperature named (Kollmann would place the critical point at 500°) the metal, though, perhaps, unaffected as to actual strength, becomes far less ductile, this property being restored at a somewhat higher temperature. Metal forged, bent, or worked under these circumstances is liable to form cracks which defy any but the most careful inspection to discover, but which, under suitable conditions, may be developed into very serious flaws. By the light of these experiments, many otherwise unaccountable occurrences may be explained. By way of illustration a case in point is given. A pump rod for a mine was rolled from Bessemer iron made from best pig, and was found to stand a satisfactory test both for ultimate strength and elongation. After a short time several lengths of the rod gave way. A careful examination of the fractured portions showed circumferential cracks extending inwards (in some cases covering half the cross-sectional area) with smooth sides, on which there was here and there observed a distinct blue colour. Chemical analysis demonstrated a good metal for the required purpose; somewhat high, it is true, in arsenic (0·048 per cent.) and antimony (0·045 per cent.), but not sufficient to impair the working properties of the metal at a red-heat; for it was proved that the iron was not in any degree red-short, nor was there difficulty in welding it. The simplest explanation of the occurrence is that the metal was worked at that temperature at which it is more brittle than when cold or red-hot: the cracks thus formed under the hammer would be developed by the shrinkage during subsequent cooling. Further experiments to ascertain the influence of foreign substances on the blue-shortness of iron and steel are greatly to be desired.—W. G. M.

On the Martin Process with exclusive or preponderating use of Pig-iron and Ore. J. v. Ehrenwerth. Zeits. f. Berg. u. Hüttenw, **34**. 656.

FROM the experiments quoted the following conclusions are drawn:—1. The ores do not act directly but chiefly by the agency of the slag. 2. By the increased amount of slag from the exclusive use of pig and ore the heat of the bath is diminished, and the time of duration of a charge lengthened, and thus the lining is more strongly attacked, demanding more repairs, especially since the slag is rich in oxide of iron. 3. The reaction between the slag and the iron is accelerated at high furnace temperatures, and the charge is thus worked off more rapidly. 4. This process is much more dependent on the working temperature than is the ordinary process. 5. The ore should be supplied in small pieces, which will rapidly dissolve in the slag, rather than in lumps or briquettes of pig-iron and ore. 6. An ore of low oxidation is preferred because a larger amount may be used, thus leading to a higher yield of iron, but otherwise the degree of oxidation is of no importance. A great excess of slag with its attendant evils may be in part avoided by rapidity of work, by the use of high-class refractory materials and suitable fluxes, and by tapping the slag when its action is completed. In cost of working, this process, rightly carried on is at least on a par with Bessemer's, whilst in regularity of production, floor space required, absence of blast, and for low carbon metal, is actually superior to it.—W. G. M.

Improvements in the Preparation of Materials for, and in the Manufacture of, Cupels and Tests. F. Maxwell Lyte, Putney. Eng. Pat. 10,185*, August 27, 1885. 6d. (Amended Specification.)

THE amendment consists in an alteration in the title of a specification abstracted in this Journal for 1885, page 538.—W. G. M.

Improvements in Steel Converter Linings and Bottoms. A. E. Tucker, Birmingham. Eng. Pat. 14,507, Nov. 26, 1885. 4d.

BASIC Bessemer slag, alone or mixed with lime or iron oxide, cast into blocks, rammed into bricks, or used as a slurry, may be employed with advantage for lining the body and top sections of steel converters, or either copper, lead and glass furnaces or iron cupolas.
—W. G. M.

Improvements in Separating the Precious Metals from Lead. T. J. Greenway, Sheffield. Eng. Pat. 1027, Jan. 23, 1886. 6d.

THE "zinc skimmings" from the zinc desilvering process are first liquated in the usual way to separate the excess of lead; if the resulting metal contain less than seventy-five per cent. of lead, it will on fusion separate into two layers, of which the upper will be an alloy of sixty per cent. zinc, with over twenty per cent. precious metals and less than six per cent. lead, and the lower will be lead saturated with this alloy. On cooling, the argentiferous zinc first solidifies, and is to be removed, broken up, and retorted. The lead bath during cooling gives up a further quantity of the zinc alloy in the form of crystals, which may be treated in the same manner as the zinc crust.—W. G. M.

Manufacture of Refractory Bricks, Tiles, Tubes, Crucibles, Furnace Linings, and other Articles subjected to High Temperatures. A. Fould and P. Genreau, Nancy, France. Eng. Pat. 1243, Jan. 27, 1886. 6d.

CERTAIN modifications are described, but the method preferred by the patentees is to incorporate thoroughly calcined dolomite in the form of powder with eight per cent. of an agglomerant, made by fusing "molecular" weights of calcium, magnesium, or sodium chloride, or of cryolite with "equivalent" weights of calcium or sodium carbonate, or of lime: this mixture to be then, if necessary, recalcined to expel all traces of water and carbon dioxide, afterwards pressed into the required shape and fired for four hours, when it will have become hard, and may, if in a covered place, be preserved long in air without deterioration. During the firing, unless before moulding the ingredients have been fired at a white heat, some shrinkage will occur. Lime, magnesia, or alumina may be used instead of dolomite, provided care be taken to expel the whole of the carbon dioxide and water before moulding. The agglomeration may also be effected by slaking the base with a solution of chlorides, and subsequently calcining thoroughly.—W. G. M.

Improvements in the Purification of Iron, and of Phosphatic Ferruginous Slags. T. Twynam, London. Eng. Pat. 1796, Feb. 6, 1886. 6d.

THE melted pig iron is run into a reverberatory furnace with basic or neutral lining, and there treated with basic slag, the metallic oxides of which are reduced by the metalloids of the pig. When the iron is so rich in silicon that the slag will finally contain more than twenty to twenty-five per cent. of silica, phosphoric acid will be reduced, the phosphorus passing into the metal: in this case the siliceous slag must be tapped off and fresh slag added, or if preferred the desiliconised iron may be treated by the Thomas-Gilchrist or Siemens process.—W. G. M.

Improvements in the Smelting of Tin Ore and Recovering Tin from Tinned Sheet Iron Scraps. G. T. Lewis, Philadelphia, U.S.A. Eng. Pat. 3138, March 5, 1886. 8d.

THE tin ore is smelted in a cupola furnace, from which the gases, containing much volatilised tin, are sucked by a fan through sheet-iron cooling chambers, and then forced through a series of woollen bags which intercept the tin compounds. The latter may subsequently be treated in any suitable way. The temperature of the furnace, more especially if tin scrap be under treatment, should be high, in order to assist the volatilisation of the metal.—W. G. M.

XII.—PAINTS, VARNISHES, AND RESINS.

Improvements in the Manufacture of Paint. F. Wendling, Munich, Germany. Eng. Pat. 1086, Jan. 25, 1886. 6d.

IN order to prepare a washable paint able to resist atmospheric influences, the patentee forms a binding body by finely pulverising and mixing together the following substances:—about 30 parts of potash or soda water-glass, 15—25 parts of fluoride of calcium, 10 parts of cryolite, between 15 and 10 parts of marble or silicate of magnesia, between 20 and 15 parts carbonate of lime, 10 parts phosphate of lime. 100 parts of colouring matter are thoroughly mixed with 200 parts of the binding body, and 1 part of this mixture is added to 2 parts of caustic potash with sufficient water to form the proper consistency. The paint is applied in the ordinary way. To harden the paint it is washed with warm water containing about 15 per cent. potash or soda water-glass.
—B. H.

XIII.—TANNING, LEATHER, GLUE, AND SIZE.

Reinsch's Tanning Process by means of "Alkaline Coal Extract" (Pyrofuscin). Dingl Polyt. J. **262**, 79—83.

THIS new tannin, composed of carbon, hydrogen and oxygen, exists in almost all coal (except anthracite), but in varying quantities. Its chemical reactions have been partly studied by the author (this Journal, 1885, 392). Its stability, when acted upon by strong chemicals and light, distinguishes it from most humic acid bodies. It is extracted from suitable coal by a boiling alkaline solution, in which it is readily soluble, and from which the "pyrofuscin" is precipitated by a mineral acid. Pyrofuscin is a weak acid, its alkaline salts being easily soluble, and alkaline-earth salts less soluble. By evaporating the potassium and sodium salts, microscopic, indistinct rhombic crystals are obtained. On boiling with concentrated chromic acid solution a weak acid of yellow-brown colour is formed. Pyrofuscin is a very stable body; its dilute or concentrated solutions in alkalis remain unaltered in contact with the air; neither concentrated hydrochloric nor sulphuric acid attack the pure substance. On the other hand, boiling nitric acid converts it into a body soluble in water. The alkaline solution of pyrofuscin is very antiseptic. A very dilute solution (0·02grm. of the moist substance per litre) exposed to the long-continued influence of direct sunlight is not chemically altered or discoloured. The direct extract from coal obtained by frequent boilings of the coal with caustic soda (about 100grms. caustic soda to 2—3kilos. coal) contains at least 2—3 per cent. pyrofuscein, and has a sp. gr. of 1·025—1·03. A hide, after treatment with the pyrofuscin solution, is converted into leather. This leather has a stronger grain, and withstands alternate wetting and drying much better than alum or bark-tanned leather. If tanned sheeps' skins be laid for twenty-four hours in a 2—3 per cent. pyrofuscein solution, they are greatly improved as regards firmness and toughness. Hides intended to be tanned with pyrofuscein are unhaired with lime in the usual way, and then the lime is removed by a bran "bate." The hides are then soaked for two to three days in a pyrofuscein solution containing about 25grms. per litre, and afterwards placed in a solution containing about 40grms. per litre, to which is added sodium carbonate (10grms. per litre) and slaked lime (20grms. per litre), in which they remain three to five days. They are then laid in a solution of two parts by weight of common salt and three parts of magnesium chloride in sixty parts of water, to which is added twenty-four parts by volume of hydrochloric acid This solution neutralises the alkali and precipitates the pyrofuscein in the fibre of the hide. The hides are then washed, lightly oiled, and dried. This process is said to be 50 per cent. cheaper as regards time and material than bark-tanning, and 30 per cent. cheaper than alum.—B. H.

Improvements in the Manufacture of Leather. W. R. Earp, Runcorn. Eng. Pat. 2052, Feb. 12, 1886. 6d.

THE patentee claims the use of an alkaline solution of a sulpharsenate or sulpharsenite, disulpharsenate or disulpharsenite, preferably the sodium salts, or a mixture of them containing five to eight parts sulpharsenical salt to 100 parts of water for unhairing hides. He also claims the use of sulphurous acid, or a bisulphite, in tanning, and adds about a gallon sulphurous acid solution at 4½° Tw. to a tan-pit of average size.—B. H.

XIV.—AGRICULTURE, MANURES, Etc.

Action of Sodium Nitrate as a Manure. V. Magerstein. Bied. Centr. **15**, 581—583.

IN the experiments described, sodium nitrate was applied to potatoes, barley and oats, on a sandy soil, which had received a light dressing of superphosphate. In some cases the nitrate was mixed with the soil, in others it was used as a top dressing, after sowing the seed, and when the plant had sprouted. Potatoes and oats yielded best with the top dressing, whilst with barley the contrary was the result. The rainfall during the period of growth (April to August) was 347·7mm. somewhat below the average. The weight per bushel and the ash of both the oats and the barley were greater in the case of top dressing. The author gives an explanation of this behaviour of sodium nitrate. In the case of top dressing the nitre dissolves in the moisture of the soil, and forms a tolerably concentrated solution there. This comes first in contact with the shallower rooted barley, oats and potatoes. The conditions in the other mode of manuring are different, hence the different results.—D. A. L.

Comparative Manurial Experiments with Ammonium Sulphate and Sodium Nitrate. V. Magerstein. Bied. Centr. **15**, 583—585.

OATS and barley were grown on a diluvial sandy soil, with 200kilos. sodium nitrate per hectare, and with 300kilos. ammonium sulphate per hectare. The yield per hectare was as follows:—

	NO MANURE.		SODIUM NITRATE.		AMMONIUM SULPHATE.	
	Straw. Kilo-ctr.	Grain. Hectolit.	Straw. Kilo-ctr.	Grain. Hectolit.	Straw. Kilo-ctr.	Grain. Hectolit.
Barley	15·85	18·28	24·50	26·41	24·62	23·71
Oats	27·50	28·47	39·80	38·72	48·45	35·41

Ammonium sulphate on this light soil favours straw production, but nitrate is superior as regards grain. The percentage of ash in the barley straw was:—Unmanured, 6·605; with sodium nitrate, 6·151; with ammonium sulphate, 5·205. In the oat straw:—Unmanured, 10·016; with sodium nitrate, 8·123; with ammonium sulphate, 6·861. From a financial point of view the nitrate proved the best.—D. A. L.

Value of Chili Saltpetre as a Manure. A. Stutzer. Bied. Centr. **15**, 585—597.

THE present article is the first part of a prize essay, written for the Committee of Nitrate of Sodium Producers. The original treatise is divided into two parts. 1. Manuring with nitrogenous substances with special reference to sodium nitrate. 2. The practical application of sodium nitrate as a manure. The essay represents fully the present state of our knowledge of this subject, and is, therefore, of much interest. First, the absolute necessity of nitrogen to plant life is indicated; and, after due consideration of the question of the need of a store of nitrogen in the soil, the following conclusion is given: That no plant cultivated on farms will grow normally unless nitrogen is supplied through the roots. Without nitrogenous manure plants grow but feebly, therefore such manure becomes necessary; and as the manure produced on farms in by far the greater number of cases is not sufficient for the requirements of crops, if really a good harvest is sought, nitrogenous manures must be used. The numerous nitrogenous manures of commerce are mentioned, nitrate being selected as best, ammonium sulphate coming next. Then the conditions necessary for the formation of nitric acid in the soil are detailed. Nitrates being the only form of nitrogen immediately assimilable by plants, sodium nitrate is specially adapted for producing vigorous nutrition and growth of plants; then owing to its mobility in soil it acts as a manure to the subsoil, and causes the roots to penetrate into the soil, and so make better use of the moisture and nutritious matter contained in it. Loss of sodium nitrate by drainage is referred to. Numerous instances of the injurious action of large quantities of ammonium sulphate on plants are compared with the few instances of such injury by sodium nitrate; in fact, injurious impurities frequently present in ammonium sulphate are never found in sodium nitrate. The following table gives, in round numbers, the mean excess of the increase in yield obtained by the use of 100kilos. sodium nitrate when compared with the increase in yield from 75kilos. ammonium salts:—

			Experiments.
25kilos.		wheat grain and 100kilos. straw	88
50	,,	barley grain and 100kilos. straw	81
150	,,	meadow hay	28
200	,,	potatoes	36
900	,,	sugar beat	144
1700	,,	mangold...............................	36

The last column of numbers indicates the number of experiments from which the averages were obtained. The advantage of using phosphates and potash salts in conjunction with sodium nitrate is explained. The next point considered is the quality of the produce after the use of nitrogenous manures. With regard to oats and barley, the albuminoids in the grain are increased 1 per cent. This is beneficial for distilling and feeding, but undesirable for brewing purposes. The albuminoid increase in the straw is quite unimportant. The effect of nitrogenous manuring on the bread-making qualities of wheat requires investigating. Authorities disagree as to whether the weight of grain per bushel is or is not affected by such manures. The quality of potatoes is not altered to any noteworthy extent when nitrate is sown with the seed, but when it is applied as a top dressing there is a decline both in the yield of tubers and in the quantity of starch in them. Sugar beet is even more sensitive than potatoes to the action of sodium nitrate, when the known limits are exceeded ; directions for the cultivation of sugar beet are given. The idea that sodium nitrate impoverishes the soil is shown to be fallacious, for experimental evidence demonstrates that sodium nitrate only occasions a need of more plant nutriment in quantities necessary to supply the requirements of the increased barvest it itself produces ; but this produce is not richer than usual in mineral matters ; and, moreover, sodium nitrate does not aid the washing out and removal of important plant foods, and by that means impoverish the soil. Lawes and Gilbert show that barley grown with nitrate does not remove more matter from the soil than barley grown with ammonium salts. Numerous experiments show that on an average the amount of straw produced by nitrate is not excessive when compared with the total produce. Numerous calculations are given as to the relative value of sodium nitrate for different crops. With sugar beet, the 1st, 2nd, 3rd and 4th hundred kilos. of sodium nitrate, per hectare, each produce 2324kilos. of roots, the 5th and 6th hundred kilos. each produce only 975kilos. ; therefore, it is not economical to use more than 400kilos. of sodium nitrate per hectare. Experiments with oil-plants, pulses, fodder-plants, meadow grass and fibre-plants are too few to afford matter for positive generalisation, but it seems that the profits from nitrogenous manuring on meadow grasses are nil, while for rape they are very high. The comparative action on summer and winter crops requires investigating. According to the results of scientific investigation and practical experience, the following may be regarded as the average amount of increased produce by manuring with sodium nitrate in average quantities and under average agricultural conditions :—Corn crops, 300kilos. grain, 500kilos. straw; potatoes, 1200kilos. ; sugar beet, 2300kilos. ; and mangold, 4000kilos. ; for every hundred kilos. nitre used. Meadow grasses take up nitrogen as readily as corn crops, but the increase produced is not so valuable, since it takes as much manure to produce 100kilos. of grass as it does to produce 100kilos. of barley-corn ; therefore, it is only under very favourable conditions of soil and market that it would pay to manure meadows with sodium nitrate. The smallest return for nitrogenous manuring is offered by leguminous crops such as peas, vetches, lupins, clover, etc. With regard to other crops there are no trustworthy data, but from general experience rape, mustard, poppy, maize, millet, buckwheat, hops, tobacco, cabbages, flax, and hemp may be classed with corn crops ; the vine and all fruit and berry-bearing plants are also very sensitive to nitrogenous manurings. A lower but still considerable profit may be anticipated in return of manuring carrots, chicory, parsnips, wild cabbage, and artichokes with nitrate of soda. With regard to the use of this manure on very porous soils, it should only be used as a top dressing, the best time being when the plant is just appearing above ground ; it may, however, be put on at a later period of growth. The question of autumn or spring sowing is not yet definitely decided ; but it seems best to divide the allotted quantity of nitrogenous manure, putting the smallest lot on in the autumn, and the larger lot in the spring, at any rate the nitrogen required for the winter growth of crops may, without hesitation, be applied in the form of nitrate of soda.—D. A. L.

Ammonia in Turnips. L. Battut. Bied. Centr. **15,** 604—607.

When turnip juice or slices of turnip are distilled with calcined magnesia (Boussingault's method), ammonia is given off. Juices from different turnips yield per 100grms. of root, 2·37, 1·67, 5·00, 1·53, 1·28mgrms., or a mean of 0·00215grm. ammonia. Fresh root cuttings give 0·9, 1·69, 0·97mgrms., or a mean of 0·0012grm. ammonia. Roots dried at 100—110 give more ammonia than fresh roots, evidently owing to the decomposition of organic matter. The following results show that, besides ammonia, the roots contain easily decomposable nitrogenous matter. Some fresh root gave, by the above method, 0·00169grm. ammonia ; the residue treated with lime-water, and the original volume made up with water, then distilled as before, gave a further 0·0204 per cent. of ammonia ; and this residue, in its turn, treated with potash, etc., and distilled, yielded a further 0·0061 per cent. ammonia. Pellet and Morchais suggested that the ammonia was present as ammonium magnesium phosphate, and therefore recommend treating with nitric acid before distilling with magnesia ; this treatment is, however, evidently quite inadmissable in the presence of such decomposable substances.—D. A. L.

Manurial Experiments with Oats. Bied. Centr. **15,** 642—643.

These experiments demonstrate that when the manures contained nitrogen, phosphoric acid and potash, or nitrogen and phosphoric acid, the plants were darker in colour, the straw longer and more perfect in grain ; but took eight days longer to ripen than in the following cases. With phosphoric acid and potash manures the plants at first showed no difference, but later on the green corn was more yellowish, and ultimately the straw was weak. Unmanured plants were worse than the others in all points, and had to be harvested earlier. The money value of the increase in yield in each case was :—With sodium nitrate, superphosphate, and potash, 93·38 marks (about £4 13s. 4d.) ; with sodium nitrate and superphosphate, 66·64 marks (about £3 6s. 7d.) ; with a moderate quantity of superphosphate and potash, 41·62 ; with larger quantity superphosphate and potash, a deficiency of 1·42. Potash manures made least show ; probably the soil contained sufficient already.—D. A. L.

Composition of Barley and Peas. Klien. Bied. Centr. **15,** 644.

The author has observed a decrease in the amount of albuminoids in barley and pea-corn, when grown on a sandy soil poor in lime, with large quantities of superphosphate. On the other hand, this was not observable when such soil was heavily dressed with precipitate (neutral phosphates), nor in the case of a soil rich in lime, even when ten times as much superphosphate was applied. Moreover, on a phosphorite soil, containing 20 per cent. of phosphoric acid, the amount of albuminoids in peas was not less than when they were grown with a slight dressing of phosphatic manure. Wagner found on a sandy soil poor in lime, heavily manured with superphosphate, that the albuminoids increased in straw and green plants, but decreased in grain and seed. It is hence inferred that the traces of free mineral acid, and not the great excess of combined phosphoric acid in the soil, impede the migration of the albuminoids in such cases.—D. A. L.

Disintegration of Basic Cinder by Exposure to Air. Edmund Jensch. Chem. Zeit. **10,** 1271—1370.

The author's experiments prove that during the disintegration which Thomas-slag undergoes by exposure to damp air, the phosphoric acid of the slag becomes more and more soluble in alkaline citrate ; so that after the lapse of, say, one year in contact with moist soil, it may be supposed that the whole of the phosphoric acid of the slag will be converted into a form in which it is immediately assimilable by plants.—J. M. H. M.

The Solubility of Thomas-slag. M. Maltzan. Chem. Zeit. **10**, 1337–1338.

The author criticises the papers of Reis and Meyer (this Journal, 1886, 381) on the solubility of Thomas-slag in aqueous solutions of carbonic acid, and holds to his statement that this slag "contains phosphoric acid in the most insoluble form conceivable." According to Reis' experiments, 22·839grms. of a saturated aqueous solution of carbonic acid are needed to dissolve 1grm. of phosphoric acid from Thomas-slag. One of Meyer's experiments gives a solubility of 1 in 34,000 in fifty hours. Considering that 2936 parts of a saturated aqueous solution of carbonic acid dissolve 1 part of phosphoric acid in artificially prepared tricalcium phosphate in ten hours, and that the solubility of the phosphoric acid in bone-ash is 1 in 13,158, and of that in bones buried for twenty years 1 in 7299, the author considers the experiments referred to to be decidedly in support of his statement.

—C. A. K.

On the Valuation of Slag from the Thomas Process, according to the fineness of the Ground Product. M. Fleischer. Rep. Anal. Chem. **6**, 673–681.

It is now well understood that the value of this slag, both for meadow-land and tilled fields, depends upon the fineness with which it is ground; and hence it is important in purchasing it that the fineness or percentage of fine-ground slag should be specified. It is usual in many places to stipulate that at least 75 per cent. should pass through a sieve the holes of which are 0·25mm. broad; but the results obtained by sifting specimens of the same slag often vary considerably, this being due to differences in the kind of sieve employed. The writer has been in the habit of using a sieve of sheet-metal in which holes of 0·25mm. in diameter were punched; whereas, at other places, wire sieves are employed, the distance between the wires being 0·25mm. In the former case, the area of the opening is 0·049sq. mm., in the latter, 0·063. He has carefully investigated the manner in which the determination is affected by (1) the nature of the sieve, (2) the duration of the shaking, and (3) the weight of the sample taken for sifting. Sieves with punched holes are unsuitable for the purpose, as the holes soon get stopped up; but the brass-wire gauze does well, and is very uniform. The particular kind of gauze selected was that known as No. 100; the distance between the meshes of this is 0·168mm., and the area of the holes 0·028sq. mm. The following method of estimation is recommended:—

The whole of the sample is weighed, and first sifted through a coarse sieve so as to remove the particles over 1·5mm. in size; these are weighed and allowed for afterwards. From the coarsely-sifted slag a sample of 50grms. is taken and shaken for half-an-hour in a sieve made of No. 100 wire-gauze. The residue is weighed, and the difference between this and 100 gives the required percentage—weighing the sifted slag gives too low a result, as some of the fine dust is always lost. Samples should contain at least 75 per cent. of "fine-ground slag," for although the sieve above recommended is finer than those at present used, the grinding of the slag is now more carefully carried out than was formerly the case.

The following example will show what compensation should be paid in case the slag does not come up to the specified degree of fineness. Suppose that 10,000kilos. of slag are sold for 360s., 20 per cent. of phosphoric acid and 90 per cent. of "fine-ground slag" being guaranteed. This corresponds to $\frac{9000 \times 20}{100} = 1800$kilos. of phosphoric acid in the "fine-ground" for 360s., or 1kilo. of fine-ground phosphoric acid for 0·20s. If the slag is found to contain only 19 per cent. of phosphoric acid and 80 per cent. of "fine-ground," the quantity of fine-ground phosphoric acid is only $\frac{8000 \times 19}{100} = 1520$kilos., the value of which is 304s. Hence, 56s. should be paid as compensation.—D. E. J.

XV.—SUGAR, GUMS, STARCHES, Etc.

Raffinose. E. von Lippmann and others. Bied. Centr. **15**, 630–636.

This is a resumé of the numerous researches of various authors, which have appeared from time to time, and have culminated in establishing the identity of the sugar obtained from molasses, from cotton seed, and from Eucalyptus-manna, now known as "raffinose." Raffinose exists as such in the original root; in the strontium hydroxide process it separates along with the cane sugar, as a saccharate; in the diffusion process it is the cause of the formation of needle crystals. Tollens has examined solutions containing, for 100 of cane sugar, 1, 3, 5, 7, 9, 12·5, and 25 per cent. of raffinose. When these solutions are crystallised, those containing 1 per cent. deposit unaltered cane sugar, those containing 3 and 5 per cent. give elongated crystals, the 7 per cent. gives long needles, whilst the 9 to 25 per cent. solutions also yield needles, but only after some months. When the mother-liquors from the crystallisation of the 1—3 per cent. solutions are diluted, beautiful long needles gradually separate. Raffinose is hence regarded as favouring the formation of molasses, or in other words, impeding the crystallisation of sugar to a certain extent. Raffinose, $C_{36}H_{64}O_{32} + 10H_2O$, crystallises in needles with 15 per cent. of water, which can be expelled, if care be taken, without fusing the sugar. It is very soluble in water, but only very sparingly in strong or dilute alcohol; from the latter it can be readily crystallised. Raffinose only reduces Fehling solution after inversion, and then very strongly. The specific rotation of raffinose (α) D=104—105°, after 1 hour's inversion is reduced to (α) D=about 53°, and levulose is found in the syrup. After 5 hours' inversion it is only (α) D= about 20°, and galactose may be obtained from this syrup. Heated with nitric acid, raffinose yields 22—23 per cent. of mucic acid; hence, the above formula is probably correct; with sulphuric acid it yields levulinic acid. With phenylhydrazin it yields a yellowish precipitate, after 1 to 2 hours' heating. Raffinose, either before or after inversion, ferments easily and completely with yeast and solutions containing the nutritive substances for the yeast, with the formation of alcohol. It forms a sodium compound, and like cane sugar a strontium compound in hot solutions. It differs from cane sugar in not forming with smaller quantities of strontium, or in cold solutions, a mono-strontium compound. These two sugars may be separated by means of this reaction. Raffinose also forms a calcium compound. For the estimation of raffinose two methods are proposed, one based on polarisation and inversion, the other on the formation of mucic acid, by means of nitric acid. Raffinose has been detected in barley by C. O'Sullivan.

—D. A. L.

On the Production of Crystallised Grape Sugar. Seyberlich and Trampedach. Neue Ztschr. f. Zuckerind, **17**, 186.

The authors find that grape sugar crystallises from acid or neutral solutions only in fine interlaced needle-shaped crystals, retaining obstinately much mother-liquor; whilst from alkaline solutions it may be obtained in smooth, strong plates, free from water, from which the liquor may be readily separated centrifugally. They, therefore, obtain a sugar of 96 to 98 per cent., by converting 1 part of starch, rubbed down with 2 to 3 parts of water, by nitric acid (5 parts to 1000 parts of starch) until 10 drops of the solution give no turbidity with 20cc. of 96 per cent. alcohol; then neutralising with chalk and rendering distinctly alkaline by soda, evaporating *in vacuô* to 35—36° B., and cooling slowly. The separated syrup may be evaporated and again crystallised, when, after adding sulphuric acid, and separating the resulting calcium sulphate, since it contains practically the whole of the nitric acid in the free condition, it may be employed for converting a fresh portion of starch. If sulphuric acid be used for the conversion, in addition to the soda, there must be added a small quantity of hydrogen peroxide to oxidise the albuminous bodies contained in the starch.—W. G. M.

* Gmelin-Kraut. Anorg. Chem. II. 1, 368.

Determination of the Decolourising Power of Animal Charcoal. G. Laube. Rep. Anal. Chem. **6**, 660—661.

THIS is a simple process, yielding good comparative results, to avoid the costly apparatus usually employed in sugar factories. A sample of good animal charcoal is obtained, bad pieces in it being carefully picked out, ground, and then passed through a fine sieve. The powder is dried at 110° C., and is then kept as the "*standard char.*" 50—100cc. of good caramel are dissolved in an equal volume of water, mixed with 100cc. alcohol, and then made up to a litre: after standing for several days, it is filtered, and is ready for use as the "*standard colour.*" The decolourising power of the powdered "char" is determined by gently boiling 5grms. of it with 200cc. water, and then adding 10cc. of the "standard colour" solution. The boiling is continued for exactly 10 minutes, under an upright condenser. The liquid is then passed through a double filter until the filtrate is quite clear. Some of the standard colour solution is then run into 200cc. water, from a graduated pipette, until the water has exactly the same tint as the above filtrate. The tints are rendered more distinct by the addition of a drop of caustic soda, and the comparison should be made in test-tubes of equal diameter, as in Nesslerising. 10cc., less the number of cc. added in the second experiment, gives the number of cc. of "standard colour" solution, which has been decolourised by the 5grms. of standard "char." By repeating the experiment under exactly the same conditions with any other "char," its decolourising power, compared with that of the standard sample, can be readily determined. As the fineness of the powder influences the result, the same sieve should always be used for the experiments.—E. E. B.

On the Decolourisation and Purification of Sugar Juice by Hyposulphurous Acids, or its Salts. R. Englert and F. Becker. Ger. Pat. 36,851, Jan. 31, 1886.

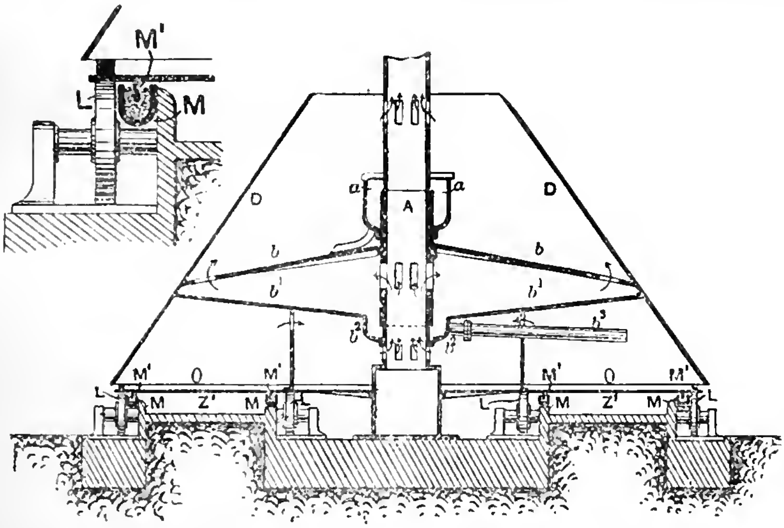
THE hyposulphurous acid with the formula, H_2SO_2, may be produced by mixing an excess of iron filings or zinc dust with aqueous sulphur dioxide solution, with exclusion of air and thorough cooling. The resulting reaction is thus expressed :— $2SO_2 + 2Zn + H_2O = SO_3Zn + SO_2Zn + H_2$. By adding milk of lime, the comparatively insoluble calcium sulphite is precipitated, and by the subsequent addition of phosphoric, oxalic or sulphuric acids, the required acid is obtained in the free condition. To prepare salts of the acid, the solution of the zinc salt should be mixed with the base to be employed, if by its action zinc oxide can be separated. The salts suitable for use in the clarification process are those of the alkali earth metals, magnesium, aluminium, zinc, manganese and iron; and these, being more stable than the free acid, are to be preferred. In practice, two to three parts of one of the salts suffice for the treatment of 1000 parts of the juice; it is thus four times more efficacious than calcium sulphite. In treating raw juice by this process, the following course is recommended:—1st saturation: The juice is mixed with 2—3 per cent. of lime, warmed and saturated with carbon dioxide to 0·10 of alkalinity, and the precipitate removed by a filter-press. 2nd saturation: 0·5 per cent. lime is added, saturation is effected, as before, to 0·04 per cent., and filtration. 3rd saturation: 1 per cent. of a hyposulphite is added, it is saturated to 0·02 per cent. of alkalinity, boiled, and filtered through double thickness of cotton cloth, under a pressure equal to 3—5m. of the juice. 4th saturation: The juice is evaporated to a thick syrup, and 2 per cent. of a hyposulphite is added, with 1—2 per cent. of milk of lime; it is then finally saturated to 0·03 per cent. by carbon dioxide, boiled and filtered. Lastly, after further boiling, a pure syrup of exceptionally high density is obtained.

—W. G. M.

XVI.—BREWING, WINES, SPIRITS, Etc.

Improvements in the Method of and Apparatus for Making Fodder from certain Liquid Waste Products. H. Henecke, J. Palm, and E. Seetig, Darmstadt, Germany. Eng. Pat. 14,459, Nov. 25, 1885. 8d.

THE closed conical receptacle D is revolved on rollers L by any suitable mechanism: the space M is a flue in connection with a furnace, the sides being rendered tight at M^1 by means of tongues or rings projecting from the under side of D into sand placed in the annular U-shaped chambers shown. The liquid refuse from breweries, etc., is fed into vessel a, from whence it is distributed upon the shelf b, from thence to b , and by pipe b^3 to the revolving heated floor O, where the evaporation commenced on the heated shelves b and b^1 is continued. The dried matter is removed from O by a scraper, and pressed between heated rollers.—C. C. H.



Chemical Characteristics of Beer manufactured from Pure Yeast. E. Borgmann. Zeits. Anal. Chem. **25**, 532—535.

HANSEN investigated the causes of the diseases of beer, and found them in some cases to be due to the yeast employed, which was contaminated with "secondary" forms. To remedy this, he proposed to prepare pure yeast—that is, yeast grown under conditions of absolute purity from a single selected yeast cell. This pure-cultivation yeast is now in use in the brewery of Old Carlsberg, and also in a great many other breweries on the Continent. At Old Carlsberg two pure yeasts are in use—No. 1 and No. 2—each of which is cultivated from a single yeast cell, and produces a beer with different distinct characteristics. Two experimental fermentations with these yeasts were carried on at Old Carlsberg. The wort used was ordinary bottom fermentation wort of 13–14 per cent. Balling, and the fermentations were so carried on that the results were comparable. After some months' storage the beers were bottled and sent to the author. Both were bright and pure flavoured. On analysis, they gave the following numbers:

Contains in 100cc.	Beer prepared with Yeast No. 1.	 Yeast No. 2.
Alcohol	1·13 grms.	4·23 grms.
Extract	5·35 „	5·84 „
Ash	0·20 „	0·25 „
Free acid (as lactic acid)	0·086 „	0·144 „
Glycerol	0·109 „	0·137 „
Phosphoric acid	0·0775 „	0·0828 „
Nitrogen	0·0710 „	0·0719 „

From these numbers, which are the mean of many determinations, the author concludes that the different yeasts cause a different chemical composition in the resulting beers. He also finds that the proportion of alcohol to glycerol is different from that found with other beers. From analyses of other beers he finds that the proportions are—

	Alcohol.	Glycerol.
Maximum	100	5·497
Minimum	100	4·140

whilst with the Carlsberg pure yeast beers the numbers are—

No. 1 Alcohol.	 Glycerol.	No. 2 Alcohol.	 Glycerol.
100	2·63	100	3·24

—G. H. M.

Composition of Old Wine. J. Moritz. Chem. Zeit. **10,** 1370.

By the analysis of some samples of Rothenberg, 1748, 1783, compared with other analyses previously made, the author shows that these old wines, especially when kept in the cask, contain a large proportion of glycerol, the maximum found being 14 glycerol to 100 alcohol. The proportions of extract and acid are also greater in the old wines.—J. M. H. M.

XVII.—CHEMISTRY OF FOODS, SANITARY CHEMISTRY, DISINFECTANTS, Etc.

(*A*) CHEMISTRY OF FOODS.

On the Presence of Nitric and Nitrous Acids in Milk, and the Adulteration of Milk with Water. M. Schrodt. Rep. Anal. Chem. **6,** 684.

The author has examined the milk of cows which have been fed for some time upon turnips to which saltpetre has been added, and finds that none of the latter passes into the milk. Hence the presence of nitric and nitrous acids in milk would tend to prove that the milk has been adulterated with impure spring water containing nitrous acid.—D. E. J.

(*B*) SANITARY CHEMISTRY.

Improvements in Apparatus for Use in Softening and Purifying Water. A. Bell, Manchester. Eng. Pat. 14,372, Nov. 24, 1885. 8d.

After the addition of the reagents required for softening the water, it is run into a tall upright tank, the upper part of which is fitted with a number of ribbed shelves, or plates, sloping to one side of the tank. The ribs on the under sides of one plate are intermediate to those on the upper side of the next plate below, which nearly touch the surface of the plates between the upper ribs. The water passing across the plate travels in a circuitous path under and over the ribs at right angles to the direction of slope. The precipitate deposits upon the shelves, slides to their lowest edge and into a pipe communicating with all the shelves, from which the deposit is periodically drawn off. The clarified softened water flows off from above the shelves.—C. C. H.

Drying of Sewage. V. L. E. Miller, London. Eng. Pat. 10, Jan. 1, 1886. 6d.

The sewage is placed in an air-tight tank so as to nearly fill the interior thereof. The space above the sewage is put in communication with a fan or pump; a pipe or pipes communicate between the outer air and the bottom of the tank, ending in perforations. A current of air can thus be drawn through the sewage, whereby the water in the sewage is "either converted into vapour or absorbed by the air, and pumped out of the tank, the more or less dry residue alone being left."—C. C. H.

Improvements in the Arrangement and Constitution of Apparatus for Extracting Sewage Sludge or other Semi-solid Matter from Tanks or Places where it Subsides or is Precipitated. J. C. Bothams, Salisbury. Eng. Pat. 530, Jan. 13, 1886. 8d.

Along the bottom of the tank is a pipe communicating with a main pipe; the underside of the branch pipe is provided with a number of projecting branches fitted with a sliding or swivel valve. The sludge can be removed from all parts, or any one part, of a tank by opening the sliding valves and sucking the sludge up into the main pipe by means of a vacuum arrangement. —C. C. H.

Improvements in Disinfecting and in Apparatus therefor. T. Bradford, Salford. Eng. Pat. 591, Jan. 14, 1886. 8d.

The disinfecting chamber is placed over a furnace, at the side and front of which is a small boiler worked at atmospheric pressure, and kept filled to a constant level with water. The steam from the boiler passes first into a superheating chamber situated in the furnace, and from thence into the disinfecting chamber.—C. C. H.

Improvements in the Treatment of Sewage. S. D. Cox and J. Cox, Bexley Heath, Kent. Eng. Pat. 1259, Jan. 28, 1886. 4d.

After separating the solids, the sewage is passed through rusty scrap-iron, and afterwards through peat or wood charcoal.—C. C. H.

XVIII.—ELECTRO-CHEMISTRY.

Electrical Conductivity in Fused Alloys. B. Rösing. Inaug. Dissert. Jena, 1886.

The opinion that electricity may be conducted in two distinct ways—(1) molecularly, when the current exerts no chemical action on the conductor; and (2) electrolytically, when the conductor undergoes chemical decomposition—receives some support from experiments by the author. He finds that if an electrical current of sufficient strength to effect a considerable rise in temperature be passed through a fused alloy, a small fraction of the current is conducted electrolytically. —C. A. K.

XX.—FINE CHEMICALS, ALKALOIDS, ESSENCES, AND EXTRACTS.

Examination of Japanese Oil of Peppermint. B. C. Niederstadt. Rep. Anal. Chem. **6,** 575.

This cheap variety of the oil has a pale yellow colour, a strong odour of peppermint, with a burning aromatic flavour, a specific gravity of 0·960 to 0·961, and a negative polarisation of 105° to 106°. It is neutral and unaffected by iodine, dissolving in one to two parts of alcohol of specific gravity 0·85, and giving with nitric acid but indistinctly the characteristic blue colour of the English oil. By the nitroprusside of copper test neither oil of turpentine, glycerol nor alcohol could be detected in it.—W. G. M.

On the Yield of Ethereal Oil of Peppermint. A. M. Todd. Pharm. Rundsch. 1886, **4**, 233.

THE quantity of oil yielded on distillation is identical whether from the fresh cut or the dried plant: and except that the latter gives a somewhat better aroma there is no practical difference in the quality.—W. G. M.

Fabiana Imbricata. C. Ochsenius. Arch. Pharm. **24**, 896.

THIS drug, recently imported into Europe from Chili, where its leaves and thin twigs are used as a remedy against the liver-fluke, common to cattle on damp pasture lands, is a plant of the Chilian *Solanaceæ* order. It is a strong, woody shrub, commonly about three feet in height, growing in dry mountainous districts between 29° and 37° south latitude at a height of 300 to 2000 metres above the sea level; its habitat being that of the tamarisk, its appearance in flower that of the erica. —W. G. M.

Researches on American Drugs. Amer. Jour. of Pharm. **16**, 417.

Xanthoxylum fraxineum.—The powdered bark, according to Edw. T. Maffet, gave with absolute alcohol 2·7 per cent. of extract, consisting of resin, with some sugar, tannin, colouring matter, and an alkaloid, which was obtained in yellowish crystals by treatment with ammonia and chloroform. The latter gave the usual reactions with alkaloid reagents, and appeared identical with that obtained by Colton, except that the latter was insoluble in chloroform.

Kalmia angustifolia.—This shrub, which acts as a strong poison with sheep, has been examined by T. J. Deibert. By treating the aqueous extract of the leaves with lead acetate, separating the lead, and extracting with alcohol, he obtained a residue which contained small crystals of a substance answering to the tests for arbutin. Considerable quantities of tannin were also found in the leaves.

Plantago major, according to D. Rosenbaum, contains a fair proportion of sugar and oxalic acid; whilst in the leaves of the plant, T. Koller found also albumen, pectin, with citric and oxalic acids.

Hamamelis Virginica.—W. B. Cheney found in this plant notable quantities of a saponifiable wax, green resin, tannin, and sugar, but no trace of an alkaloid or crystallisable body.

Smilax rotundifolia.—The bark was found by A. H. Cohn to contain a glucoside not yet isolated, but no calcium oxalate.

Equisetum biemale, F. J. Young finds to contain two resinous bodies of brownish-green colour, one semi-fluid, the other of firmer consistency. It in no wise merits its reputation as a remedy for dropsy.—W. G. M.

Indian Drugs. E. Egasse. Nouv. Remèd. **2**, 434, 462.

Chasmantera cordifolia (*cocculus cordifolius*).—Under the names of gulaucha, guloe, and giloe this plant flourishes in India, the drug being sold extensively in the bazaars as a tonic and antiperiodic, in the form of cylindrical pieces 2 to 5cm. long and 1 to 5cm. in diameter. It is a perennial creeper, climbing to the summit of the highest trees, its branches putting forth roots which, reaching to the ground, initiate a fresh growth; roots, stem, and leaves are equally in demand as a drug. The Indian pharmacopœia commends its use as a tincture (4 to 8cc. *in die*); as an extract (0·6grm. to 1grm. *per diem*, in the form of pills); and as an infusion (1 : 10) of which 60cc. to 90cc. are to be taken thrice a-day. The stems contain berberin, an uncrystallisable bitter substance changed by dilute sulphuric acid into a glucoside, and a bitter kind of starch meal known as "Palo."

Toddalia aculeata (*Paullinia aculeata*), one of the family of *Rutaceæ*, flourishes on the Coast of Coromandel, in Southern China, Ceylon, Java, and the Isles of Mauritius and Bourbon. All parts of the plant possess an acrid flavour when fresh: the leaves are employed to relieve pains in the bowels; and the fruit, when ripe, is used as a substitute for pepper, whilst after drying it is made into vinegar by the natives. The root has long been used as a stimulant and febrifuge, the Indian pharmacopœia recommending a tincture and an infusion, in doses of 10cc. of the former, or 3grms. to 60grms. of the latter, twice or thrice in the day. Notable quantities of a resinous body, an ethereal oil, in flavour recalling oil of cinammon, and a bitter substance, are found in the outer portions of the roots.—W. G. M.

XXII.—GENERAL ANALYTICAL CHEMISTRY.

The Separation of Zinc from Iron, Cobalt, and Nickel. P. von Berg. Zeits. Anal. Chem. **25**, 512—519.

FROM Ostwald's numbers for the relative chemical affinity of acids it is probable that zinc can be completely separated from iron, cobalt, and nickel by hydrogen sulphide in formic acid or monochloracetic acid solutions. Hampe (this Journal, 1885, 419) has shown this to be the case with formic acid. The author has examined the question under Ostwald's direction.

Precipitation in Formic Acid Solution.—Hampe found that complete separation took place when at least 15—20cc. formic acid of sp. gr. 1·2 were added to each 250—500cc. of the solution; if less were added small quantities of other sulphides came down with the zinc sulphide. From the results of Ostwald's researches it seemed probable that better results would be obtained with very much more dilute solutions, and the author found that with 3cc. formic acid, sp. gr. 1·2 in 360cc. water, a precipitate of zinc sulphide quite free from iron was obtained. The precipitation must take place at about 50—60° C., and the precipitate must be filtered off at once, as a little iron comes down on standing. The precipitation is carried out as follows: When the solution is diluted to the required strength it is warmed to 50—60° C., and sufficient formate or acetate of sodium added to combine with the whole of the sulphuric acid, the proper amount of free formic acid is then added, and hydrogen sulphide slowly passed through the solution. When precipitation is complete and the precipitate has partly settled, it is thrown on a filter and washed with hydrogen sulphide water containing one per cent. free formic acid. In the analyses given below, 51·9195grms. $ZnSO_4.7H_2O$ were dissolved in 500cc.

DETERMINATION OF ZINC IN PURE ZINC SULPHATE SOLUTIONS.

	ZnO taken. Grm.	FOUND.		Formic Acid. sp. gr. 1·2. cc.	Total Solution. cc.	Difference in per cent.
		ZnS. Grm.	ZnO. Grm.			
1.	0·2940	0·3532	0·2950	1·0	100	+0·33
2.	0·2910	0·3526	0·2915	1·0	100	+0·16
3.	0·2940	0·3525	0·2944	2·5	300	+0·14
4.	0·2940	0·3524	0·2941	2·5	300	+0·02
5.	0·2940	0·3518	0·2938	5·0	300	−0·06
6.	0·2940	0·3505	0·2927	7·5	300	−0·43
7.	0·2940	0·3483	0·2909	10·0	300	−1·03

These numbers show that zinc can be completely precipitated from formic acid solution as zinc sulphide if the amount of free acid present is not too great. For the determination in presence of iron, 5cc. of the above solution were taken, mixed with 1·2grm. of iron-alum, diluted with water to required strength, warmed to 50—60°, and treated as above.

DETERMINATION OF ZINC IN PRESENCE OF IRON.

	Taken.		Found.		Volume of Solution. cc.	Formic Acid cc.	Difference in per cent.
	ZnO. Grm.	Iron alum Grm.	ZnS. Grm.	ZnO. Grm.			
1.	0·1470	1·2	0·1777	0·1181	200	2·8	+0·96
2.	0·1470	1·2	0·1772	0·1180	200	2 8	+0·68
3.	0·1470	1·2	0·1765	0·1174	280	2·8	+0·26
4.	0·1470	1·2	0·1762	0·1472	280	2·8	+0·11
5.	0·1470	1·2	0·1760	0·1470	360	3·6	−0·01
6.	0·1470	1·2	0·1758	0·1468	360	3·6	−0·12

The precipitates in Nos. 1 and 2 contained a little iron; in Nos. 3 to 6 they were quite free from iron.

DETERMINATION OF ZINC IN PRESENCE OF NICKEL.

	Taken.		Found.		Vol. of Solution. cc.	Formic Acid. cc.	Difference in per cent.
	ZnO. Grm.	$NiSO_4$. Grm.	ZnS. Grm.	ZnO. Grm.			
1.	0·1470	0·25	0·1768	0·1477	360	3·6	+0·47
2.	0·1470	0·25	0·1765	0·1474	360	3·6	+0·27
3.	0·1470	0·25	0·1761	0·1471	360	3·6	+0·06

These analyses were carried out exactly as before; no trace of nickel was found in either precipitate.

DETERMINATION OF ZINC IN PRESENCE OF COBALT.

	Taken.		Found.		Vol. of Solution. cc.	Formic Acid. cc.	Difference in per cent.
	ZnO. Grm.	$CoSO_4$. Grm.	ZnS. Grm.	ZnO. Grm.			
1.	0·1470	0·25	0·1764	0·1473	360	3·6	+0·22

3.	0·1470	0·25	0·1753	0·1464	360	3·6	−0·40

In the precipitation of zinc in the presence of cobalt the precipitate, after a time, becomes slightly green. It is necessary, therefore, to dissolve the precipitate, after filtration, in hydrochloric acid in order to separate the small amount of cobalt sulphide it contains. The acid solution of zinc is then neutralised with ammonia, treated as above, and the pure zinc sulphide weighed.

Precipitation from Monochloracetic Acid Solution.—The analyses with this acid were carried out as follows:—The solution made up to the required volume was warmed to 50—60° C., 4cc. of a double normal solution of ammonia (34grms. NH_3 per litre), and 7cc. of a four times normal solution of monochloracetic acid (378grms. $CH_2ClCOOH$ per litre) added, and then a slow stream of hydrogen sulphide passed through the mixture. The precipitated zinc sulphide separated in a heavy powdery form and rapidly fell to the bottom of the vessel, thus allowing rapid filtration; it is necessary to filter at once, and wash with hydrogen sulphide water containing a little monochloracetic acid, or a little cobalt sulphide may come down. In analysis No. 9, as shown in the last table, the filtration was delayed fifteen minutes, with the result of getting about one per cent. cobalt sulphide thrown down.

The separation from iron and nickel is complete; with cobalt immediate filtration is required.

—G. H. M.

A New Test for the Detection of Picric Acid and Dinitro Cresol in Food. H. Fleck. Rep. Anal. Chem. **6**, 649—650.

Of late manufacturers of farinaceous foods, such as maccaroni, have been in the habit of dyeing them, usually with dinitro-cresol (Victoria yellow); since picric acid has been occasionally substituted for this harmless dye, the necessity of a test for distinguishing them has arisen, as the bitter taste imparted to such goods by picric acid is not always satisfactory evidence. The process recommended is to digest the finely-powdered sample of food with alcohol, filter, evaporate filtrate to small bulk, and then taste; if the liquid be bitter, picric acid is probably present. Warm for a few minutes with a little pure hydrochloric acid, cool, and then drop a fragment of metallic zinc into the evaporating basin. After standing in the cold from half-an-hour to two hours, the contents of the basin will become a beautiful blue colour if picric acid be present, or bright blood-red with dinitro-cresol. Mere traces of these two dyes can be detected by this test.

—E. E. B.

The Detection of Alum in Flour. J. Herz. Rep. Anal. Chem. 1886, 359.

A CYLINDER is filled from one-fourth to one-third full with the flour under examination, and the flour is thoroughly moistened with water. Then a few cubic centimetres of alcohol and two drops of a freshly prepared logwood solution (5grms. logwood in 100cc. alcohol) are added. After thoroughly mixing up the thick paste the cylinder is filled up with a saturated solution of common salt. At the same time, trials are made using pure flour and flour containing 0·01 %, 0·05 %, 0·1 % alum, and by comparing the depth of colour of the flour under examination with these standards the amount of alum in it can be estimated. The gradations of colour for each amount of alum are distinct and the colour is permanent for a day. In presence of 0·05—0·1 % alum the salt solution takes a clear blue colour; with 0·01 % the colour is a violet red. —B. H.

Examination of Red Wines for Artificial Colouring Materials. J. Herz. Rep. Anal. Chem. **6**, 650—652.

THE author prefers Blarez's method of detecting acid-magenta or other sulphonic acids. The wine is shaken up with lead peroxide, which quickly decomposes all the other colours, whilst even traces of acid magenta render the filtrate violet-red. To test for the other colours as well, 30—50cc. of the wine—either in its original condition or, preferably, after being concentrated by evaporation—is treated with 20—30cc. of a cold saturated solution of magnesium sulphate, and then 10—20cc. caustic soda solution is stirred in. The precipitate of magnesium hydrate carries down with it all the natural colouring matter in the wine, and also most of the artificial, except archil and the sulphonic acids; the former gives rise to a dark-blue filtrate, whilst the latter can be detected by treating the colourless or yellowish-red filtrate with sulphuric acid. If the filtrate be red or reddish-brown, the treatment with magnesium sulphate and soda must be repeated. By this test the acid-magenta may be detected in 30cc. of unconcentrated wine containing only 1 part in 100,000 (by weight) of it. After being well drained, the magnesium hydrate precipitate, together with the filter, is dried in a porcelain basin with some sand over a water bath. This residue is extracted with ether, and the extract tested for ordinary magenta by dyeing some woollen threads with it in the usual manner; the so-called "Cassissine" leaves a yellowish-brown colour in the basin, and dyes the wool reddish-brown, which becomes yellow with strong hydrochloric acid, and colourless with strong ammonia.

If some of the original wine be shaken up with amyl alcohol, and the extract evaporated to dryness, the colour of the residue is altered when treated with certain reagents, as shown in the following table:—

	With Concentrated Sulphuric Acid.	Concentrated Hydrochloric Acid.	Caustic Soda.
Archil, violet-red	Blue	Red	Blue
Bordeaux B, carmine	Carmine	Carmine	Carmine
Ponceau RRR, dark red	Crimson	Crimson	Brown
Cassissine, violet-purple	Yellow	Yellowish-brown	Red
Vinicoline Bordelaise, cherry-red	Brown	Red	Brown

The colour of the wine after extraction, changes in the presence of ordinary magenta to cherry-red, of magenta S. to reddish-violet, of Bordeaux to dark cherry-red, of Ponceau to yellowish-red.

To test for foreign vegetable colours, a cold saturated solution of tartar emetic is strongly recommended. 10—15cc. of the wine are shaken with 5cc. of the tartar emetic solution, allowed to stand for some hours, and then examined by reflected and transmitted light. If the wine shows a violet tint it has been artificially coloured. Experiments were made by the author with white wines, artificially coloured with various decoctions, and also with red wines, to which 20 per cent. of the artificially coloured wine had been added. When treated with tartar emetic, the following results were obtained:—

Red wine (genuine)	Cherry red.
Common red poppy (*Papaver Rhœas*)	Dark cherry red.
Cherries	Violet.
Elderberries (*Sambucus nigra*)	Reddish violet.
Dwarf Elderberries (*Sambucus Ebulus*)	Violet.
Bilberries (whortleberries)	Violet.
Privetberries	Pure violet.

The fresher the decoctions the more distinct is the reaction. An old solution of privetberries is not detected by the above test. To obtain the violet tint well, it is advisable to dilute the wine with at least an equal volume of water (if the colour be very dark more water must be added), and in all cases to compare the samples with genuine red wine, treated under exactly the same conditions. The spectroscope has not yet been found by the author to give reliable results.—E. E. B.

Notes on the Pyridine Alkaloids. Oechsner de Coninck. Compt. Rend. **103**, 640.

THE methyl- and ethyliodides of the pyridine alkaloids give delicate colour reactions in presence of caustic potash, a property not shared by the corresponding derivatives of the reduced pyridines (piperidine and its homologues). The methyliodides of aniline and its homologues give no colour reactions in presence of caustic potash. The reaction serves, therefore, to distinguish the pyridine alkaloids from the above groups. Hofmann's reaction for the pyridine bases (*Ber.* xiv. 1497) (characteristic smell on heating the methyliodides with caustic potash) is not given by the methyliodides either of piperidine and its homologues, or by those of aniline and its homologues.—C. A. K.

Determination of Tannin. E. B. Zeits. Anal. Chem. **25**, 527—528.

THE author has examined the various methods of tannin determination, and finds that Von Schroeder's modification (*Zeits. Anal. Chem.* **25**, 121) of Löwenthal's method gives the best results. The author carried out the determination, using a solution of ferrous acetate prepared from iron alum in the following proportions:—

Iron ammonium alum	48·2grms.
Crystallised sodium acetate	25·0 ,,
Acetic acid containing 50 % hydrate	10·0cc.

dissolved in one litre.

10cc. of this solution are added to 50cc. of the tannin solution to be determined, which is prepared according to Schroeder of 5grms. per litre; the mixture is examined at the end of fifteen minutes to see if the iron is in excess, which should always be the case, made up to 100cc. and filtered. 20cc. of the filtrate, equal to 10cc. of the original solution, are then titrated with standard potassium permanganate, after addition of 20cc. indigotin solution. The difference between the amount of iron added and that found on titration gives the amount precipitated by tannin. The author gets very good results with tannin and gallic acid by this method, but has not had an opportunity of trying it with other substances containing tannin.—G. H. M.

The End Reaction in Titrations with Fehling's Solution. E. Beckmann. Zeit. Anal. Chem. **25**, 529–530.

In order to determine the point at which all the copper disappears in volumetric determinations with Fehling's solution, the author recommends moistening the outside of a piece of filter-paper with a little of the filtered liquid, after folding the paper two or three times, and when it is soaked through, applying a drop or two of the reagent for copper—potassium ferrocyanide in acetic acid solution or ammonium sulphide—and then examining the paper against a white background.—G. H. M.

Estimation of Acid in Malt. E. Prior. Bied. Centr. **15**, 647.

In the ordinary way an aqueous extract is made by soaking malt in water for two hours, agitating frequently, filtering, and titrating filtrate. It is now shown that such prolonged contact with water is prejudicial to the results, since half-an-hour's action of water on malt is frequently sufficient to give rise to an abundant formation of acid. Hence the following method of procedure is recommended:—100grms. of crushed malt are left in contact with 500cc. of dilute alcohol (made by mixing commercial acid-free absolute alcohol with four volumes of water), stirred frequently and, after at least four hours, filtered. 100cc. of the filtrate are titrated with baryta water in the usual way.—D. A. L.

A New Process for Estimating Glycerin (Glycerol) in Fermented Liquids. L. Legler. Rep. Anal. Chem. **6**, 631—636.

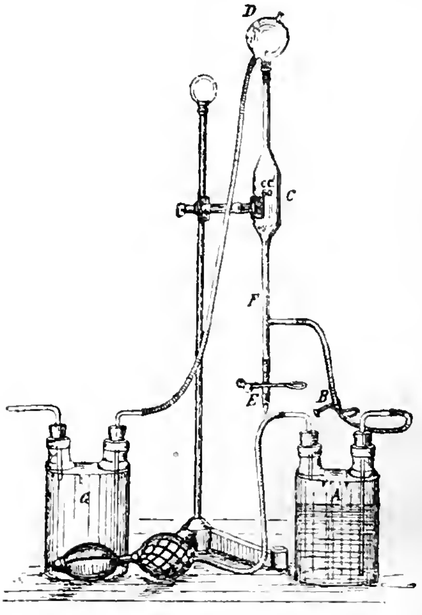
All the processes which have hitherto been proposed for determining the amount of glycerol in wine, etc., are inaccurate, since it is impossible to extract all the glycerol by means of a mixture of alcohol and ether. It is true that glycerol, if pure, is completely soluble in such a mixture; but if it contains any impurities which are insoluble the loss is frequently very considerable. To avoid this source of error, it is proposed to determine the amount of glycerol in a sample of wine by oxidising it to carbonic acid by means of a strong solution of potassium bichromate and sulphuric acid. The reaction is expressed by the equation $3C_3H_8O_3 + 7K_2Cr_2O_7 + 28H_2SO_4 = 7K_2SO_4 + 7Cr_2(SO_4)_3 + 9CO_2 + 40H_2O$. It is, however, advisable to use an excess of acid and of the bichromate. The determination can be made with a Will's carbonic acid apparatus; the mixture of the glycerol and the oxidising liquid must be allowed to boil gently until the action is complete, the gases evolved being passed through concentrated sulphuric acid. The apparatus is then cooled, and a current of dry air drawn through it. The loss in weight is due to the escape of carbonic acid, and from this the amount of glycerol can be calculated. The author recommends operating on about 1grm. of glycerol, and taking such a large quantity of strong sulphuric acid for drying the gases evolved that the mixture can be boiled for three to four hours without the loss of any aqueous vapour. The test experiments made by the author with pure glycerol are very accurate.

To determine the glycerol in a sample of wine, the impure glycerol (obtained by evaporating a known volume of the wine to dryness with milk of lime, and extracting with 96 per cent. alcohol) is oxidised as described above. The author assumes the absence of sugar, tartaric, malic, citric and tannic acids, which would evolve carbonic acid if oxidised with potassium bichromate and sulphuric acid. He makes a deduction of 0·035grm. glycerol for 100cc. wine for the other organic impurities; but, if desired, they may be first removed by precipitation with an ammoniacal solution of lead acetate, which would not interfere with the subsequent treatment of the liquid.

This method has not yet been thoroughly tried for determining the glycerol in beer or sweet wine; but to remove the cane sugar from the latter, before oxidising it, the author recommends heating the sample with baryta water, which will completely decompose the sugar, the resulting compounds being insoluble in alcohol. The results of future investigations of the subject are promised.—E. E. B.

An Ether-pipette for Fat Determinations. F. Soxhlet. Rep. Anal. Chem. **6**, 637.

The pipette, shown in the accompanying woodcut, was devised to avoid the injurious effects produced by constantly drawing off by suction the ether solutions into a pipette when the fat had to be estimated in a large number of samples of milk. The aqueous ether solution is placed in the two-necked bottle A, which is connected with an indiarubber air-syringe. If this be pressed with one hand, and then the pinchcock B is opened with the other, the ether will rise from A into the pipette C, and finally overflow into D. The cock B is then closed immediately, and the contents of the pipette allowed to run into the agitating flasks by opening E, until the liquid has fallen to the mark F. As soon as a large proportion of the ether solution is in the two-necked bottle G, owing to the overflow into D, this bottle is put in the place of A.—E. E. B.



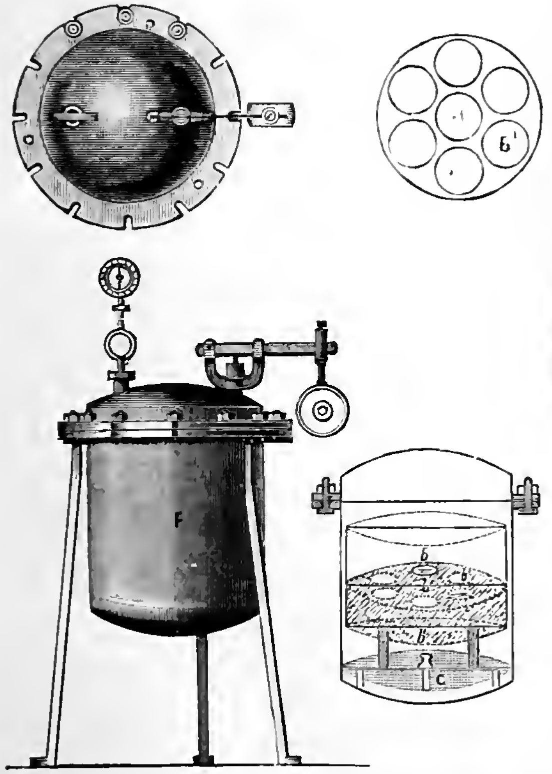
Estimation of Fusel Oil by Capillarimetry. J. Traube. Rep. Anal. Chem. **6**, 659—660.

In reply to criticisms on the author's former articles on this subject by A. Stutzer and O. Reitmar (*Rep. Anal. Chem.* **6**, 606), he denies that the ethereal oils which may be found in brandy and liqueurs, influence the height of the liquid in the capillary tubes more than ethyl alcohol, and states that consequently they would not interfere with the determination, even if present in large quantities. Only when certain acid compound ethers are present, as is the case in many ethereal oils, would the capillarity be appreciably affected, and these compounds are decomposed by the distillation with potash. The author has proved the accuracy of these statements by actual experiments with liqueurs.—E. E. B.

The Determination of Starch in Seeds, etc., by means of Soxhlet's Digester. Paul Zipperer. Rep. Anal. Chem. 699—703.

Although determinations of starch in starch-meal made by various analysts agree fairly well, the results obtained in the estimation of starch in seeds are often very discordant. Widely different results have been given by different chemists for the amount of starch contained in pepper; and whereas the percentage of starch found in cacao beans by some chemists varies from ten (Payen, Lampadius) to fourteen or eighteen (Mitscherlich), James Bell only found four or five per cent. of starch which could be converted into sugar. These differences are due to the faulty methods of analysis employed; and the writer points out that in dealing with seeds, a simple treatment with dilute acids in order to convert the starch into sugar is inadmissable, because they contain other substances (especially cellulose), which are thus converted into dextrose, and so influence the results.

Two methods of analysis are employed in agricultural laboratories. The first is that of Maercker, in which the finely-powdered substance is heated with water (Francke adds a small quantity of lactic acid) under pressure in a Reischauer's flask for some hours at 125—140° C.; it is then filtered, and after inversion with HCl, the sugar in the filtrate is determined by means of Fehling's solution. In the more recent method proposed by Faulenbach, a concentrated solution of diastase (prepared by extracting malt with glycerine and water) is employed. Both methods have disadvantages, especially when time is taken into consideration. The cover-glasses of Reischaur's flask frequently crack, owing to the unequal pressure of the screws; and Faulenbach's method seldom gives good results, because the solution of diastase soon loses its fermenting power, and becomes almost useless within a month after it has been prepared.



The author has adopted a modification of Maereker's method, in which the conversion of the starch is carried out under pressure, and the cellulose is almost completely separated. The apparatus employed is that devised by Soxhlet for the estimation of starch, and consists of a copper vessel F, 25cm. in diameter and 28cm. deep, tinned on the inside, and supported on iron feet. The disc *b* is supported by three feet, which rest upon a sieve *c* placed upon the bottom of the digester; in *b* there are seven openings *b*¹ which serve as supports for strong glass flasks of about 150cc. capacity. Water is poured into the vessel until it stands about 1cm. above the false bottom *c*, and then *b* (which is also filled with water up to the level of the holes *b*¹) is introduced. The finely-powdered substance is placed in the flasks, shaken up with a few cc. of distilled water, and 100cc. of hot distilled water added; 2grms. of meal or flour should be taken, and 2—5grms. of seeds, such as pepper or cacao. After thorough shaking the flasks are uncorked and placed in the holes *b*¹, the cover is screwed tightly on, and the temperature raised to 140—150 C., which corresponds to a pressure of four atmospheres, as indicated by the barometer. By proper regulation the temperature can be kept fairly constant for three-and-a-half hours; the steam is then allowed to escape by the safety-valve, and the cover is removed. The contents of the flasks are filtered while hot with a filter-pump, and the residue on the filter washed with hot water until the filtrate gives no reaction with iodine. The filtrate (measuring 300—350cc.) is heated with 20cc. concentrated HCl in a flask with inverted condenser on a water-bath for three hours, filtered, neutralised with caustic soda, and made up to 500cc.; the dextrose formed is estimated by titration with Fehling's solution. The percentage of starch is calculated by the formulæ given by Sachsse:—

$$\begin{array}{ccccccc} \text{Dextrose} & : & \text{Starch} & = & \text{Dextrose found} & : & x \\ 108 & : & 99 & = & y & : & x \end{array}$$

Or the percentage of dextrose found must be multiplied by $\frac{99}{108}$ = 0·916.

Seeds which contain much fatty matter should be pounded with an equal quantity of quartz-sand, placed in a cone of filter paper, and treated with ether for three hours in Soxhlet's extraction apparatus; the fatty matter can be determined in the ethereal extract. If they contain tannic acid and ready-formed sugar as well, they must undergo a further treatment for three hours with eighty per cent. alcohol, before the starch is extracted. The author gives examples of analyses in which the results differ only by a fraction of a per cent., and states the residue left after filtration gives no reaction with iodine.—D. E. J.

New Books.

TECHNISCH-CHEMISCHES JAHRBUCH, 1885—86. Ein Bericht über die Fortschritte auf dem Gebiete der Chemischen Technologie vom Juli 1885 bis April 1886. Herausgegeben von Dr. RUDOLF BIEDERMANN. Achter Jahrgang. Mit 263 in den Text gedruckten Illustrationen. Berlin: Carl Heymann's Verlag. 1887. London: H. Grevel & Co., 33, King Street, Covent Garden.

OCTAVO VOLUME, strongly bound in cloth and gilt lettered. It contains Preface, Table of Contents, List of abbreviated titles of works referred to in text, 471 pages of subject matter, with which are interspersed 263 woodcuts. Next follows a Review of New Books that have appeared during the session 1885—1886, arranged as works on Physics, Chemistry, Chemical Technology, Mineralogy, Geology, and Botany, and works on Miscellaneous Subjects. The Jahrbuch closes with carefully arranged Indexes of Names of Authors, and subject matter. The arrangement of the subject matter is as follows:—I. Gesetzgebung, Verordnungen U.S.W. II. Eisen. III. Magnesium and Aluminium. IV. Gold und Silber. V. Kupfer. VI. Blei. VII. Zink. VIII. Zinn. IX. Nickel und Kobalt. X. Mangan. Molybdan, Antimon. XI. Chlor, Salzsäure, Brom, Iod. XII. Schwefel, Schwefelwasserstoff, Schwefligesäure, Schwefelsaure. XIII. Säurrstoff, Wasserstoff, Wasserstoffsuperoxyd, Kohlensaure, Saltpetersaure. XIV. Soda. XV. Kaliumverbindungen und verschiedene Alkalisalze. XVI. Ammoniak und Cyanverbindungen. XVII. Alkalische Erden. XVIII. Thonerde und Alaun. XX. Glas. XXI. Thonwaaren. XXII. Cement. XXIII. Kunstliche Steine. XXIV. Explosivstoffe. XXV. Leuchtstoffe. XXVI. Heizstoffe. XXVII. Zucker. XXVIII. Stärke und Stärkezucker. XXIX. Wein. XXX. Bier. XXXI. Spiritus-XXXII. Fette, Harze und Seifen. XXXIII. Wasser. XXXIV. Nahrungsmittel. XXXV. Dungemittel, Abfälle, Disinfection. XXXVI. Gerberei. XXXVII. Osganische Sauren. XXXVIII. Alkaloïde. XXXIX. Farbstoffe. XL. Gespunistfasern, Cellulose, Bleichen, Färben, und Drucken, XLI. Papier. XLII. Photographie. XLIII. Apparate.

TRADE REPORT.

(From the "Board of Trade" and other Journals.)

RUSSIA (Classification of Articles in Customs' Tariff).—(Rouble=3s. 2d. Poud=36lb. av.) Syrups of white colour with yellow tinge, sweet in taste, and of sour odour, extracted from starch by treating it with sulphuric acid. Section 59, duty 1 rouble, 20 copecks per pond.

FRANCE.—Importation of Phosphorus. "By a decree of the French Government, dated the 16th December last, importers of phosphorus are required to take out '*acquits à caution*' at the post of arrival in France. These documents are to contain a statement of the quantities imported, and the name and residence of the person to whom they are addressed."

PERU.—By the new Peruvian tariff, which came into operation on the 1st of January last, the following are the revised rates of Customs' duties levied on various articles imported into Peru:—

To pay an ad valorem duty of 10 per cent.

Quicksilver
Sperm and Seal Oil
Colza Oil
Sulphuric Acid
Tar and Pitch
Roman Cement
Detonators for Mines
Scientific Instruments
Resin
Printers' Ink

GREEK CUSTOMS TARIFF.

FLOATING EXHIBITIONS.—The project for a floating exhibition at Bordeaux has been abandoned, in consequence chiefly of the Bordeaux Chamber of Commerce having declined to give its support to the undertaking.

REMARKABLE DEPOSIT OF SULPHUR.—Sulphur deposits of vast extent and remarkable purity have recently been discovered in the neighbourhood of Tarawera Mountain, the scene of the late volcanic disturbances. The deposits occur in the Onepu Block, and are all within an area of about 500 acres. Upwards of one-fourth of this area—or 125 acres—is covered with sulphur in a nearly pure state, and varying in depth from 3 or 4 to 15 feet. The sulphur exists in the form of well-developed crystals, aggregated in masses, and presents a good, clean, yellow colour. In some of the deposits there is a crust of several inches of fused sulphur, on breaking which the crystalline variety can be shovelled out. In other parts of the area referred to several feet of stones and earth have to be removed before the sulphur is reached; but all over the various deposits it can be obtained with very little trouble, and averaging 85 to 95 per cent of pure sulphur.

The deposits have long been known to the natives, but it is only recently that Europeans have had their attention drawn to them, and at present a company, having secured from the native owners a lease, is working the district. The only work necessary in recovering the sulphur, consists in shovelling it into barrows and wheeling it a few hundred yards to the river Tarawera, which runs past the Block, and is navigable thus far from the sea, a distance of 12 or 15 miles. A small steam barge is employed for carrying the sulphur down the river to Matata, where it is transhipped into larger vessels.

The district described is about 150 miles by sea south of Auckland, on the river Tarawera, and near the shores of Lake Rotoiti Te Pak. It is about 15 miles distant from the ill-fated Maori village—Moura—which, with its inhabitants, was destroyed during the recent volcanic disturbance.—*Brit. and Col. Druggist.*

TRADE MARKS IN GERMANY.—A decision in connection with German trade mark law of considerable interest to manufacturers has recently been arrived at. In Germany, under the Trade Mark Law of 1874, it has always been held that trade marks consisting solely of letters, figures, or words cannot be registered. So far as this affected native manufacturers outsiders could have no cause of complaint, but when the Commercial Tribunal at Leipsic decided that foreign trade marks of this description, however stringently they might be protected at home, were also debarred from registration, the case became very different. Obviously well-known English houses could not change the distinctive word by which their goods were known all over the world for the sole purpose of bringing themselves within the German law; and the consequence was that a system of wholesale piracy was carried on in connection with trade marks of this nature. As a result of this, not only did our manufacturers lose trade, but their wares were discredited because of the low-priced imitations bearing the same letter or word, which were palmed off as being the real English article. When the negotiations for the conclusion of an International Convention for the protection of industrial property came to an abortive conclusion, another strenuous effort was made to upset the ruling of the Leipsic Tribunal. This has at length been attended with complete success, the third section of the Imperial Court having decided that, whilst the limitation holds good as regards natives, any foreign trade mark, of whatever description, would, if properly protected in the country of its origin, be also entitled to registration in Germany.—*Chemist and Druggist.*

PERIODICAL RETURNS OF IMPORTS AND EXPORTS.

IMPORTS and EXPORTS into and from the undermentioned COUNTRIES in the latest Month for which RETURNS have been received, with Aggregates for the Period of the Year, including such latest Month.

BOARD OF TRADE RETURNS.

For the year 1886 the imports into the United Kingdom amounted to £319,381,000, a decrease of £21,023,000, or a little over 5½ per cent., as compared with 1885. More than three-fourths of the reduction is in articles of food and drink. The exports amounted to £212,361,000, a decrease of £681,000, or about ⅓ per cent. Most classes of articles show reductions. During the first half of the year trade was very bad, and foreign commerce was no exception to the rule; but during the last few months a decided improvement has set in. The imports showed a decrease of £19,086,000, or over 10 per cent., for the six months ended June 30th, while the exports for the same period showed a decrease of £1,036,000, or about 1 per cent., as compared with the first half of 1885. During the last six months, however, the decrease in the imports was only £1,237,000, or at the rate of only 1 per cent., and the exports showed an increase of £355,000.

The Board of Trade Returns for last month show a small decrease in the exports. The imports amounted to £31,011,000, an increase of £57,000, or about a ¼ per cent., and the exports to £17,051,000, a diminution of £151,000, or about 1 per cent. Nearly all the dutiable articles show increases in the quantities taken out for home consumption.—*Brit. and Col. Druggist.*

LAST MONTH'S TRADE STATISTICS.

The Board of Trade Returns for December show the following figures:—

Imports.

	December, 1885.		December, 1886.
Total value	£30,953,588	......	£31,011,283

Exports.

	December, 1885.		December, 1886.
Total value	£17,204,128	....	£17,053,510
Foreign and Colonial produce (partly estimated)	5,172,782	......	1,596,559

Below are the details affecting drugs and chemicals:—

HEMATITE ORE.—The requireme[illegible] sul[illegible]tch makers of hematite pigs are reported to be such [illegible]hovelled [illegible] certain to be a large trade in the importation of Spa[illegible] stones [illegible] the Clyde during the whole of the present year, for w[illegible]hed; b[illegible]od, indeed, sales have been made in some cases by [illegible] litt[illegible]ts. Ore-freights from Bilbao to the Clyde have recently imp[illegible]ed from 5s. 3d. to 6s. 3d. per ton.—*Chemist and Druggist.*

BERLIN.—A report of the Berlin Chamber of Commerce states that European commerce is feeling more and more the influence of the United States. The export of German corn has decreased by 50 per cent., and Mannheim, which at one time was one of the principal markets for cereals, has lost much of its importance. The sugar industry is everywhere in a precarious state. The cotton trade, chemicals and colours have greatly suffered. At the conclusion the report protests strongly against the protectionist policy of most of the European countries, and points out the disastrous consequences for Germany.—*Chemist and Druggist.*

ROUMANIA.—THE PAPER MANUFACTURE AND TRADE IN ROUMANIA AND SERVIA.—The manufacture of paper is, as stated by the Brussels *Bulletin du Musée Commercial*, only slightly developed in Roumania. Nearly all the paper consumed there is imported from Austria-Hungary, France, Germany and England. There are only two paper factories in Roumania, one at Busteni, producing about 250,000kilos. per annum; the other at Letea, established with the support of the Government, from whom it has obtained great privileges. The expenses of the construction of the latter, the property of the Roumanian Paper Manufacturing Company, and the great outlay for works to protect it from the inundations of the Bistritza, which flows at a short distance from the factory, are, however, so great that the result is most unsatisfactory, in consequence of which the shares can be got at a discount of 50 per cent. This company is, under a contract, compelled to supply all the paper the Government requires, but it is hardly able to supply the paper necessary for the printing of the *Moniteur Officiel*, and produces, therefore, barely 150,000kilos. per annum. The factory at Busteni produces likewise only paper for printing purposes. Every variety and quality of paper is consumed in Roumania. Of foreign countries, Austria-Hungary imports the largest quantity, amounting in value to 1,970,695 francs. Next follows France with 487,529 francs, Germany with 291,128 francs, and England with 43,271 francs. In Servia there is no paper factory at all, most of the paper used being imported from Austria-Hungary. In 1881 the importations were as follows:—(1) Of ordinary paper, 617,912kilos.; value 295,421 francs. (2) Of writing, printing and drawing paper, 212,630kilos.; value 290,202 francs. (3) Of cigarette paper, 53,336 kilos.; value 68,960 francs. (4) Of coloured paper, 84,145kilos.; value 80,031 francs. (5) Of card pasteboard, etc., paper, 30,102kilos.; value 57,638 francs. Payment is made by bills of exchange at four or six months. The customs duty on entry into Servia is: on silk paper, 10 francs *ad valorem*; on post paper 10 francs per 100kilos.; on thin packing paper, 8 francs *ad valorem*; on drawing paper, 8 francs *ad valorem*;

on writing and printing paper, 7 francs per 100kilos.; cardboard, 4 francs per 100kilos.; on ordinary packing paper, 4 francs per 100kilos. The customs charges do not exceed 1 per cent.—*Chemist and Druggist.*

ANALYSES OF CINCHONA BARKS

Grown in the Madras Government Plantations, and forwarded to the Indo-Colonial Exhibition, London, 1886, by David Hooper, F.C.S., Government Quinologist.

	Sulphate of Quinine.	Quinine.	Cinchonine.	Quinidine.	Cinchonidine.	Amorphous Alkaloids.	Total.

Monthly Patent List.

I.—GENERAL PLANT, APPARATUS, AND MACHINERY.

APPLICATIONS.

1886.

16715 F. N. Mackay, Liverpool. Apparatus for refrigerating enclosed spaces, such as cold stores. December 21

16780 J. H. Lorimer, London. Drying machines. December 21

16816 R. Johnson, Bradford. Method of and apparatus for compressing air. December 22

16817 J. T. Naylor, Bradford. Valve for steam, water or gas. December 22

16855 A. Firth, Sheffield. Improvements in the grates of steam-boilers and other furnaces. December 23

16863 F. Livet, London. An improved generator for the production of steam with efficiency and economy. December 23

16947 S. Pearson, Bradford. Hot-water heating apparatus. December 28

16994 H. E. Newton, London—From W. M. Deutsch, United States. Filtering apparatus. Complete specification. December 28

17015 C. A. Backstrom, London. Improvements in centrifugal machines. Complete specification. December 28

17037 W. J. Thomas, London. Improvements in pressure gauges. Complete specification. December 29

17100 A. Dervaux, London. A purifying apparatus for steam boilers. Complete specification. December 30

17133 D. Hancock, D. C. Hancock, and A. H. Hancock, London. Construction of valves for hot and cold water and other fluids. December 31

17152 J. Tangye and R. J. Connock, London. Apparatus for compressing air or the like. December 31

1887.

208 W. F. Pamphlett, London. Evaporating and condensing apparatus for producing fresh water from sea water, for drinking purposes and for boiler feed. January 6

231 G. M. Page, London—From D. Morgan, South America. An improved furnace bar. January 7

265 P. C. Vivien and A. Laine, London. Improvements in the process of and apparatus for distilling. January 7

281 J. Parkes and J. Parkes, Birmingham. Carburetting apparatus. January 8

501 P. Ewens, London. Improvements in or connected with furnaces for heating air preparatory to its use in what is known as the cool air drying process. January 12

519 M. F. Ryden, London—From C. Qvarnstrom, Russia. An apparatus for burning liquid fuel, applicable as a smith's hearth, and for other purposes. January 12

560 W. Whittaker, London. Mechanical stokers for supplying fuel to the furnaces of steam boilers. January 13

561 E. Perrett, London. Means or apparatus employed in connection with filters for the purpose of cleansing the same. January 13

592 J. B. Stubbs, Manchester. Self-acting water expellers or steam traps, applicable also as a low-pressure indicator for steam boilers. January 14

601 T. Taylor, London. Improvements in or applicable to steam boilers for consuming smoke. January 14

669 Zehren Freres, Paris. An improved form of tap or cock for water, steam, or gas purposes. January 15

673 W. Beaumont, London. Improvements in gas taps and water taps. January 15

677 A. Arnold and W. H. Webb, London. Open boilers or coppers. January 15

*COMPLETE SPECIFICATIONS ACCEPTED.**

1886.

672 A. Neubecker. Refrigerating apparatus. January 19

731 J. R. Shearer. Filters applicable for the filtration of water and other liquids. January 19

2408 H. A. Fleuss. Freezing and refrigerating machines. December 24

2520 J. Thomson. Apparatus for indicating or regulating temperature, pressure, or volume of confined fluids. December 24

2927 H. E. Newton—From E. Theisen. Apparatus for cooling and condensing purposes. January 5

3020 W. Beesley and J. Beesley. Steam boilers applicable for utilising the waste heat from puddling, forge, mill, and other furnaces. January 5

3316 H. A. Galliers and F. Klaerr. Apparatus for heating water by gas. January 8

3326 A. M. Clark—From P. Oriolle. Process and apparatus for distilling water. January 8

3420 G. A. Jarvis. Improved basic bricks. January 19

3617 C. A. Tew. Taps for governing the flow of liquids. January 19

3730 C. W. Burton and F. T. Moison. Improvements relating to the purification of water. January 19

3779 J. Love. Furnace bars and attachments thereto. January 19

1511 W. Schmidt. Steam generators and apparatus connected therewith. January 12

4693 G. Daverio. A refrigerating apparatus for roller mills. January 19

5693 F. J. Crossley. Rotary fan or propeller for the movement of air for ventilating, blowing, etc., also for the movement of fluids and gases. January 8

6531 W. Foulis. Apparatus for heating by gas. January 19

8917 J. Phethean. Apparatus for generating motive power. January 5

11624 H. Gerdes. Apparatus for supplying steam boilers with water. December 31

15215 H. J. Allison—From J. H. Blessing. Apparatus for purifying water. December 31

15216 H. J. Allison—From J. H. Blessing. Water purifying apparatus. December 31

15263 A. J. Boult—From N. Carvalho. Apparatus for heating air, steam, etc. December 24

15292 G. Westinghouse, jun. Thermostats. December 21

15715 J. Joly and J. Bochon. Apparatus for granulating or disintegrating coke, etc. January 5

15778 C. A. Knight. Apparatus for heating and purifying the feed water supplied to steam boilers. January 5

16263 W. R. Dennis. Heating apparatus. January 12

16277 E. Seger. Centrifugal apparatus. January 12

16414 W. W. Popplewell—From J. Trueb. Thermometric regulators for heating apparatus. January 15

16433 D. Rylands and R. Potter. Construction of port mouths of regenerative gas furnaces. January 19

---

* The dates given are the dates of the Official Journals in which acceptances of the Complete Specifications are advertised. Complete specifications thus advertised as accepted are open to inspection at the Patent Office immediately, and to opposition within two months of the said dates.

II.—FUEL, GAS, AND LIGHT.

APPLICATIONS.

1886.

16899 G. Tolson and J. Illingworth, Halifax. Means or apparatus for producing gas, and combining such apparatus with gas engines. December 24

16930 A. Fritschi and E. Beautils, London. The manufacture of hydrogen. December 24

16955 A. Eckford, Edinburgh. An improved automatic oil gas, etc., apparatus for lighting, gas engines, portable and other purposes, without the use of a gas-holder. December 28

16992 R. S. Lawrence, London. Improvements in carburetors and gas generators. Complete specification. December 28

17020 G. Tolson and J. Illingworth, Halifax. Gas purifiers. December 29

17021 W. C. Haigh and A. A. Haigh, Manchester. Artificial fuel. December 29

17143 G. A. Skinner, London. Apparatus for heating apartments. December 31

1887.

31 J. A. Yeadon and R. Middleton, Leeds. Machinery for the manufacture of blocks or briquettes of fuel or materials for smelting or analogous purposes. January 1

131 P. Greyson and A. Verley, London. Composition for preventing the accumulation of deposits in the retort pipes of gas apparatus or for facilitating the removal of such deposits. January 1

218 A. Chadwick, Sale. An improved fuel by the admixture of pitch and coke. January 7

411 T. Ray, Sunderland. A means of preventing explosions in petroleum or paraffin, or other mineral oil tanks. January 11

509 E. Edwards, London — From A. Lego, France. Machinery for manufacturing compressed bricks or blocks of artificial fuel. January 12

610 J. Lyle, Glasgow. Burning mineral and other oils for heating and lighting purposes, and appliances connected therewith. January 14

626 G. Rook, London. Machinery for charging and drawing gas retorts. January 14

670 J. Broad & Sons, and G. C. Fowler, London. Improvements in night lights. January 15

740 A. Kitson, London. Improvements in gas apparatus and process for generating illuminating gas. Complete specification. January 17

COMPLETE SPECIFICATIONS ACCEPTED.

1886.

1807 W. S. Morland. Removing and discharging the material used in gas purifiers. January 8

2641 G. Delaporte. Improvements in lighting by gas, and in apparatus therefor. December 24

2807 S. W. Allen and G. Breflit. Apparatus for the manufacture of artificial fuel. December 31

3058 J. A. Yeadon and R. Middleton. Machinery for the manufacture of artificial fuel, etc. January 5

3581 J. A. Yeadon and R. Middleton. Machinery for the manufacture of artificial fuel, etc. January 12

15013 J. Lilley and F. Metge. Manufacture of artificial fuel. January 8

15189 A. J. Boult—From W. P. Lane and A. M. Sutherland. Manufacture of gas. December 24

15478 F. Lux. Purification of illuminating gas, etc., and apparatus therefor. December 31

IV.—COLOURING MATTERS AND DYES.

APPLICATIONS.

1886.

16774 R. G. Price, J. Harvey, and A. J. Dodd, London. An improved manufacture of colouring matter. December 21

17083 J. Y. Johnson, London—From the Farbenfabriken vormals F. Bayer & Co., Germany. Manufacture of azo-dyes. December 30

17132 J. R. Geigz, London. Production of blue colouring matters. December 31

1887.

126 H. J. Walder, London. Process for the production of colouring matter from carbolic acid and other hydrocarbons. January 4

127 H. J. Walder. Process for producing colouring matter from anthraquinone. January 4

737 O. Imray, London—From the Farbwerke vormals Meister, Lucius & Bruning, Germany. Manufacture of colouring matters by the action of nitroso-derivatives of secondary aromatic amines upon phenols and oxycarbonic acids. January 17

COMPLETE SPECIFICATION ACCEPTED.

1886.

3198 J. Y. Johnson — From the Actiengesellschaft Farbenfabriken vormals Bayer & Co. Manufacture of azo-dyes and benzidine and tolidine mono-sulpho acids. January 8

V.—TEXTILES, COTTON, WOOL, SILK, ETC.

APPLICATIONS.

1886.

16787 W. H. Beck, London—From C. Delerne, France. Process and apparatus for washing and preparing wool and other fibrous materials. Complete specification. December 21

17080 J. Obozinski, Liverpool. New or improved waterproof, vegetable, animal or mineral fabrics, and process of manufacturing the same. December 30

1887.

611 C. Scheibler and O. Bluth, London. Manufacture of lacquered leather-like material from felt. January 14

639 F. A. Gatty and J. Leemann, Manchester. Improvements in woven fabrics, and in the method of treating the same for the production of patterns or designs thereon. January 15

COMPLETE SPECIFICATIONS ACCEPTED.

1886.

2417 J. Howgate & Sons, and F. Smith. Method of and apparatus for producing Astrachan yarn. December 24

3065 R. W. Thom. Starching and finishing textile fabrics, and apparatus therefor. January 5

3755 W. S. Johnston. Manufacture and softening of linen, hemp, jute, or other yarns. January 8

3957 H. Birbeck—From T. F. Peppé. Treating "tussur" and other wild silk cocoons, and applying the silk therefrom to the manufacture of lace, etc. January 19

14367 E. W. Serrell, jun., and E. Fourgeirol. Process and machinery for preparing silk cocoons for reeling. January 19

VI.—DYEING, CALICO PRINTING, PAPER STAINING, AND BLEACHING.

APPLICATIONS.

1887.

171 W. Birch, Manchester. Apparatus for washing, soaping, dyeing, and dunging woven fabrics. January 6

443 G. Jagenburg, London. An improved process and apparatus for dyeing unspun textile fibres. January 11

COMPLETE SPECIFICATIONS ACCEPTED.

1886.

2732 H. Kershaw. Dyeing textile goods. January 19

3758 W. Cockcroft. Apparatus for producing designs on textile piece goods. January 19

VII.—ACIDS, ALKALIS, AND SALTS.

APPLICATIONS.

1886.

17101 G. Kamensky, London. See Class XVIII.

1887.

62 W. Donald, London. Treatment of hydrochloric acid gas for the production of chlorine gas. January 3

329 O. von Gruber, London. Process for manufacturing sulpho-phosphates of ammonia and potassium. Complete specification. January 8

553 H. Porter, London. Manufacture or preparation of a compound of soda or potash and lime adapted for use in the purification and softening of waters, and for other purposes. January 13

629 D. G. Fitzgerald. See Class XVIII.

COMPLETE SPECIFICATIONS ACCEPTED.

1886.

65 L. Mond. Obtaining ammonia and hydrochloric acid from ammonium chloride. December 21

66 L. Mond. Obtaining ammonia and chlorine from ammonium chloride. December 24

1018 L. Mond. Obtaining ammonia and hydrochloric acid from ammonium chloride. January 8

1019 L. Mond. Obtaining ammonia and chlorine from ammonium chloride. January 8

1831 A. MacDonald Graham. Manufacturing sulphates of metals from their oxides. January 12

1881 J. J. Hood and A. G. Salamon. Preparation of sulphate of alumina. January 15

2207 H. J. Leslie—From R. Finch. Concentration of sulphuric acid, and apparatus therefor. January 8

3406 E. F. Trachsel. Production of carbonate of sodium or of potassium, and hydrate of strontium, or of barium. Jan. 12

VIII.—GLASS, POTTERY, AND EARTHENWARE.

APPLICATIONS.

1886.

16833 W. D. Clift, London. Manufacture of porcelain and metal baths. December 22

16877 W. Boulton, London. Apparatus for making bats for use in the manufacture of various articles of pottery. Complete specification. December 23

17115 J. L. Napier, A. D. Brogan, and A. M. Malloch, Glasgow. Manufacture of plate glass. December 31

1887.

87 W. H. Hales, Stoke-on-Trent. Machinery for making pottery ware. January 4

120 W. H. Turner, London. Improvements in the printing or decorating of earthenware, china, and the like, and in the preparation or manufacture of materials therefor. January 1

178 J. Van de Loo, Berlin. Construction of presses for the embellishment of bricks or other ceramic products. Complete specification. January 12

576 P. M. Justice, London—From La Société Anonyme des Manufactures de Glaces, Verres, Vitres, etc., Belgium. Apparatus for handling crucibles, such as those used for the melting of glass. January 13

662 O. Paterson, Glasgow. Rendering enamel paintings on stained glass impervious to atmospheric, destructive, or injurious influences. January 15

COMPLETE SPECIFICATIONS ACCEPTED.

1886.

2855 H. S. Sant and S. Sant. Process for mosaic or other decoration of pottery ware by the use of skeletons of leaves, or other parts of plants, trees or vegetables, or of insects, etc. December 31

3119 W. Cartlidge and H. Cartlidge. Enamel, lustre, and hardening kilns used in the manufacture of pottery ware. January 12

3972 W. E. Chance. Machinery for the manufacture of sheets of rippled glass. January 19

8713 M. H. Blanchard. Manufacture of ornamental and other tiles. January 19

IX.—BUILDING MATERIALS, CLAYS, MORTARS, AND CEMENTS.

APPLICATIONS.

1886.

16922 E. Clarke, Leeds. Improvements in briquettes. December 21

16926 E. A. Bronson, London. Compounds for coating and finishing walls and the like. Complete specification. December 21

17055 J. Tall, London. Admixing or combining ingredients and producing a compound suitable for exterior surfacing or facings of concrete structures or concrete articles used in buildings. December 29

17098 W. Sonnet, London. An improved mode of and apparatus for continuously manufacturing Portland cement. Complete specification. December 30

17130 A. Mack, London. Plaster boards for use in the immediate construction of dry and fireproof rooms. December 31

17158 S. P. Wilding, London—From Stamme & Co., Germany. Manufacture of briquettes. Complete specification. December 31

1887.

315 G. G. M. Hardingham, London—From P. J. Grouvelle, France. Manufacture of what is known as "iron cement." January 8

421 W. White, London. Improvements in roads and pavements, and paving blocks therefor. January 11

577 P. M. Justice, London—From C. Dietzsch, Germany. Manufacture of cement. January 13

578 P. M. Justice—From C. Dietzsch. Furnaces or kilns for calcining or burning limestone, lime, and similar materials. Complete specification. January 13

589 J. M. Murphy, Liverpool. Fireproof construction. January 11

628 J. F. O'Connor Wood, London. The disintegration of clay. January 11

642 F. V. Hadlow, Buxted. A new artificial stone or cement. January 15

678 E. W. Jones and C. Brand, London. Manufacture of paving blocks from scoria or slag, and means to be used therefor. January 15

684 F. U. Benekendorff and C. Yüngst, London. Improvements in roofing tiles. January 15

731 T. Royle, London. Treating wood with antiseptic and preservative fluids. January 17

COMPLETE SPECIFICATIONS ACCEPTED.

1886.

1126 C. D. Alison. Manufacture of cements or plasters. December 31

3217 J. B. Hannay. See Class XVII.—B.

5026 J. B. Warwood and J. Wallis. Apparatus for sifting cement, etc. January 19

X.—METALLURGY, MINING, ETC.

APPLICATIONS.

1886.

16758 C. Puddefoot, London. Seaming machines for sheet metal. Complete specification. December 21

16788 W. L. Purves, Wimbledon. Steel tempering. December 22

16790 T. C. Sanderson, London. Process for reducing antimonial ores and for separating gold and silver therefrom. December 22

16869 D. Sinclair and G. Johnstone, Glasgow. An improved solder bar or block. December 23

16870 J. H. Noad and H. R. Hammond, London. Production of aluminium from clay alumina or any of the salts of aluminium. December 23

16882 G. F. Redfern, London—From M. Raty and E. Lambert, France. Improvements in treating slag, and the like. December 23

16923 E. Veasto, London. Improvements in and apparatus for cleaning or pickling metals, and in utilising the liquids that have been employed therefor. December 24

16935 E. de Pass, London—From La Societe Industrielle et Commerciale des Metaux, France. A process for preserving the surface of copper or its alloys. December 24

16951 J. J. Robins, Derby. Forming deep corrugations in steel, iron, or other metals, to ensure sharp edges. December 28

16991 A. J. Boult, London—From J. Walton, United States. Coal-mining machines. December 28

17008 T. Archer, jun., and T. O. Robson, London. Apparatus for watering or wetting, and laying dust in the workings of mines, or for analogous uses. December 28

17049 K. W. E. Mornhu, London. Treating slag and recovering metal therefrom. December 29

17107 H. N. Penrice, London. Machinery to be used in rock tunnelling. December 30

17129 A. B. Southall and J. H. Clegg, Sheffield. Machinery, apparatus, and appliances for screening, sorting, cleaning, washing, and travelling coal and other minerals, and the like substances. December 31

1887.

24 R. Oswald, Talk-o'-the-Hill. An improved safety lamp. January 1

38 A. Gay, London. Means and apparatus for extracting iron, steel, or other magnetic substances from China-stone or other materials. January 1

63 W. H. Beck, London—From M. Marcus and C. Finaly, France. Process for the manufacture of alloys of aluminium and copper or tin for the purpose of obtaining aluminium gold and aluminium silver. January 3

105 C. Parker, London—Partly from H. L. Gault, United States. Improvements in converters used in the manufacture of steel. January 4

129 L. Plom and J. D'Andrimont, London. Blasting or breaking down coal and other minerals or rocks, and in apparatus employed therefor. January 4

247 R. Riley, Habergham. Improvements in or applicable to miners' lamps. January 7

251 H. Davis and A. Davis, London. Improvements in miners' safety lamps. January 7

260 J. Nicholas and H. H. Fanshawe, London. Improvements in the reduction of ore. January 7

285 E. Hunt, Glasgow—From G. Thomson, United States. Obtaining silver from ores, mattes, or compounds containing it. January 8

298 T. Allen, Reading. Method of forging or shaping articles of metal or other substances. January 8

301 O. Zadig and E. Feldtmann, London. Treatment of refractory ores for the extraction of gold, silver, copper, or zinc by thermo-hydro-electricity. January 8

331 J. Vavasseur, London. Steel projectiles for piercing armour-plates. January 8

382 T. C. Sanderson, London. Means and apparatus for reducing metallic oxides. January 10

433 J. Beveridge, London. Treatment of minerals and production of by-products therefrom. January 11

447 H. J. Haddan, London—From M. Neuerburg, Germany. Improvements in crushing apparatus. January 11

463 H. H. Lake, London—From W. White, United States. Improvements relating to ore separators. Complete specification. January 11

482 E. Whitehouse, Bilston. Rolling metal tubes of various sections direct from the forge, bar, billet, pile, or ingot, at one heat, process, or operation. January 12

616 Sir I. Lowthian Bell, Bart., London. Manufacture of alloys of aluminium with iron. January 14

621 H. H. Lake, London—From J. Illingworth, United States. Manufacture of metal ingots, and apparatus therefor. Jan. 14

629 D. G. FitzGerald. See Class XVIII.

630 J. H. Darby, London. Process for the manufacture of certain kinds of steel. January 14

631 J. H. Darby. Manufacture of steel or iron by the basic process January 14

657 M. Settle, Manchester. Improved apparatus for "shot firing" in mines or other places liable to the accumulation of explosive or inflammable gas, or the like. January 15

704 H. Hall, London. Apparatus and process for coating sheets, plates, and pieces of iron and steel or other metal with tin, terne, and other metals. January 17

738 C. D. Abel, London—From A. Klonne, Germany. Apparatus for screening or sorting ores and other materials. January 17

COMPLETE SPECIFICATIONS ACCEPTED.

1885.

15954 G. Lowry. Machines for crushing stone, ore, etc. December 24

1886.

310 H. C. S. Dyer. Manufacture of compound armour plates. January 8

1010 E. Morewood. Coating iron and other sheets, plates, and pieces with tin or other metal. January 12

2867 J. H. Johnson—From La Societe Anonyme de Commentry-Fourchambault. Manufacture of iron and steel. December 31

3261 W. Potthoff. Manufacture of metal castings, and apparatus therefor.

3157 W. D. Allen. Furnaces for melting and treating pig-iron, and feeding or charging same. January 15

3684 C. Clarke. Producing a "coloured gold" surface on articles of gold or other metal or alloy. January 19

3836 A. Kurzwernhart and E. Bertrand. Method and apparatus for casting ingots of steel or ingot metal. January 5

3867 A. M. Clark—From H. Harmet. An improved basic lining for metallurgical apparatus. January 5

10241 H. H. Lake—From E. Thomson. Welding of metals, and apparatus therefor. January 5

11413 M. Settle. Electric safety lamps for use in mines. January 12

11756 S. Gratrix. Apparatus for the manufacture of lead or other metal pipes. January 12

12861 J. Warwick. Treatment of fume in lead works. January 15

14928 J. R. Whitney. Improvements in and connected with the casting of metals. December 21

15154 J. T. King—From H. Kennedy. Manufacture of mineral wool, and apparatus therefor. December 24

15246 F. B. Felt. Manufacture of iron bars, plates, etc. December 24

15270 F. A. Herbertz. Cupola smelting furnaces. Dec. 24

15357 J. T. King—From D. Brose. Making steel. Dec. 31

XI.—FATS, OILS, AND SOAP MANUFACTURE.

APPLICATIONS.

1886.

16925 Sir D. L. Salomons, London. An improved buoyant soap. December 24

16979 A. W. MacIlwaine, London. Apparatus for extracting oils by volatile solvents. December 28

1887.

1 R. Tervet, Glasgow. Apparatus for treating or purifying paraffin wax. January 1

16 R. Wright, Chesterfield. Angelic cuticle and washing soap. Complete specification. January 1

198 M. Mackay. See Class XVII.—C.

360 A. G. Wass, London. An improved lubricant. Jan. 10

588 W. S. Somers, Liverpool. The manufacture of solidine or solidified burning and other oils grease. January 11

608 R. G. Price, J. Harvey, and A. J. Dodd, London. An improved manufacture of soap. January 11

COMPLETE SPECIFICATIONS ACCEPTED.

1886.

2762 E. Edwards—From L. Rivière. Process for the saponification of fatty bodies. December 21

3614 A. W. MacIlwaine. Means for extracting oils by volatile solvents. January 15

XII.—PAINTS, VARNISHES, AND RESINS.

APPLICATION.

1887.

207 R. J. Worrall, London. Improvements in the preparation of distemper. January 6

COMPLETE SPECIFICATIONS ACCEPTED.

1886.

3636 A. C. Ireland and J. R. Bowbear. Composition for preventing attachment of barnacles to the bottoms of plated ships. January 15

15561 W. Carter. Anti-fouling compostion for ships' bottoms. December 31

XIII.—TANNING, LEATHER, GLUE, AND SIZE.

APPLICATIONS.

1886.

16832 H. Buczkowski, London. Polish or coating (soluble in water) for leather. December 22

16894 J. Straighton, Liverpool. Apparatus for burring and cleaning hairy and woolly skins, and for unhairing and softening skins. December 24

17026 J. H. G. Langenhagen, Liverpool. A new or improved leather polish. Complete specification. December 29

1887.

646 W. P. Kermann and G. A. Kermann, Liverpool. An improved composition for dressing leather. January 15

COMPLETE SPECIFICATIONS ACCEPTED.

1886.

9604 W. Ross. Application of a material produced by the treatment of waste leather. January 19

15200 H. H. Lake—From A. Miliochau and F. Chailly. Improved process of tanning. December 24

XIV.—AGRICULTURE, MANURES, ETC.

APPLICATIONS.

1886.

16866 J. H. Barry. See Class XVII.—B.

17000 A. W. Carlson, London. A process and apparatus for utilising urine as manure. December 28

XV.—SUGAR, GUMS, STARCHES, ETC.

APPLICATIONS.

1886.

16775 B. J. B. Mills, London—From A. Fayaud, France. A new process for the vulcanisation of pure caoutchouc in sheets or in articles made therefrom. December 21

16827 H. Vivien, London. Apparatus for the manufacture of refined sugar, partly applicable to the manufacture of glucose, starch, and similar products. December 22

16921 J. Anderson, jun., London. Compound for use as a substitute for indiarubber, or to be compounded therewith. December 24

17011 R. Campbell, Glasgow—From J. Foster and J. Campbell, Java. Improvements in and connected with triple effect evaporating steam vacuum pans used for boiling sugar, and for other evaporating purposes. December 29

1887.

165 C. D. Abel, London—From Messrs. Pfeifer and Langen, Germany. Method of extracting foreign substances, in particular raffinose, from sugar solution by means of lead, either in the form of oxide or as electrode. January 5

256 W. Powell and E. Powell, Liverpool. A compound to be used for making adhesive paste. January 7

602 R. A. Robertson and J. G. Hudson, Glasgow. Improvements in sugar-cane mills. January 14

COMPLETE SPECIFICATIONS ACCEPTED.

1886.

3196 R. Englert and F. Becker. Process for purifying saccharine juices. January 8

14117 C. N. Waite. Compound for use in preparing starch or flour size for yarn, textiles, etc. January 12

16016 F. Scheibler. Moulding sugar, and apparatus therefor. January 8

XVI.—BREWING, WINES, SPIRITS, ETC.

APPLICATIONS.

1886.

17013 N. Browne, London—From A. Braconier, France. Manufacture of champagne and foaming wines, and apparatus therefor. December 29

17059 W. Gerdes, London. Improvements relating to the treatment of the waste products of breweries for the production of alcoholic liquor. December 29

1887.

51 P. Weinig, London. Malt germinating apparatus. Jan. 3

265 P. C. Vivien and A. Laine. See Class I.

328 B. J. B. Mills, London—From C. Brada, United States. Improvements in malt kilns. Complete specification. Jan. 8

521 E. Beanes, London. An improvement in the treatment of wines of the port and claret class. January 12

COMPLETE SPECIFICATIONS ACCEPTED.

1886.

2627 A. W. Gillman, S. Spencer, and E. S. Spencer. Apparatus for treating grain or cereals to be used in brewing, distilling, and vinegar-making. December 24

2629 A. W. Gillman, S. Spencer, and E. S. Spencer. Apparatus for steaming grain or cereals to be used in brewing, distilling, and vinegar-making. December 31

14312 A. J. Boult—From C. F. Elze. Beer refrigerators. January 19

XVII.—CHEMISTRY OF FOODS, SANITARY CHEMISTRY, DISINFECTANTS, Etc.

APPLICATIONS.

A.—Chemistry of Foods.

1886.

16929 M. Ross, Glasgow. Improvements in and connected with the drying and withering of tea-leaf, and apparatus therefor. December 24

16950 R. Glover, Stratford. An improvement in dog biscuits. December 28

17017 M. Samelson, London. Manufacture of liquid extract of coffee. December 28

17016 J. P. Larieux and H. Gregoire, London. An improved food for cattle and other animals. December 29

17075 C. S. Boynton and W. J. van Patten, London. An improvement in the preparation of food products. Dec. 30

17087 A. B. Imrie, Glasgow. Refrigerating machinery applicable to air-cooling or freezing machines for use at sea or on land, for preserving meat or other perishable substances. December 30

17136 G. F. Redfern, London—From J. Petit, France. Stoppering or closing bottles, jars, and like vessels for containing preserved food. December 31

1887.

122 H. F. von Konitz and J. Zuntz, London. Manufacture of extract of coffee. Complete specification. January 4

216 W. Olsson, London—From G. Bergman, Sweden. Improvements in food for herbivorous animals prepared from fish and vegetable substances. January 7

712 J. M. Fletcher, Cheadle. Apparatus for compressing and preserving vegetable products. January 17

B.—Sanitary Chemistry.

1886.

16866 J. H. Barry, London. Treatment of excreta, urine, and sewage sludge for the production of manure, and apparatus for use in such treatment. December 23

1887.

402 H. Schlichter, London. Platinum lamps for deodorising and disinfecting purposes. January 11

C.—Disinfectants.

1886.

16729 F. Goddard, Nottingham. Construction and arrangement of apparatus for disinfecting by steam. December 21

16831 F. H. Weber, London. Process for the manufacture of candles for fumigating or deodorising. December 22.

1887.

198 M. Mackay, London. A new deodorising and disinfecting oil. January 6

276 C. T. Kingzett, London. The production of solutions for use as antiseptics, disinfectants, deodorants, oxidants, and general sanitary reagents. January 7

381 J. C. Stevenson and J. G. Tatters, London. An improved disinfectant and oxidising agent. January 10

451 R. V. Tuson, London. Combination of ingredients, and the production of "powders" therefrom, for disinfecting and deodorising purposes. January 11

COMPLETE SPECIFICATIONS ACCEPTED.

A.—Chemistry of Foods.

1886.

2909 C. Hansen. Treatment of rennet. January 5

9690 I. Grun. Preparation of preserves for making milk and flour dishes of all kinds. January 12

11835 G. F. Redfern—From L. J. Eriksson and E. J. R. Nordling. Manufacture of dry rennet. December 24

B.—Sanitary Chemistry.

1886.

2439 F. H. Danchell. System of treating sewage. Jan. 12

3217 J. B. Hannay. Treating sewage and making cement. January 5

C.—Disinfectants.

1886.

15201 J. Watt. An improved deodorising material. December 24

XVIII.—ELECTRO-CHEMISTRY.

APPLICATIONS.

1886.

16739 C. G. Curtis, F. B. Crocker and S. S. Wheeler. Electric motors and dynamo-electric machines. Complete specification. December 21

16810 T. Goodman, London—From C. Gossner, jun., Germany. Improvements in galvanic elements. December 22

16823 E. Barbier and M. Leclanché, London. Improvements in electrical batteries, and in the manufacture of depolarising bodies to be used therein. December 22

16865 L. R. Davies and M. Shearer, London. Improvements in batteries for lighting and other purposes. December 23

16936 A. J. Boult, London—From F. L. Pope, United States. Improvements in or relating to dynamo-electric and electrodynamic machines December 24

16942 J. D. F. Andrews, London. Apparatus for the conversion of electrical currents. December 24

17018 M. H. Smith, Halifax. Improvements in and appliances for a method of transmitting electric currents. December 29

17056 G. Kapp, London. Improvements in dynamo-electric machines. December 29

17101 G. Kamensky, London. Manufacture of caustic soda, or potash, or carbonate of sodium, or potassium, together with sulphuric acid, by means of electrolysis. December 30

17120 R. E. B. Crompton and J. Swinburne, London. Dynamo-electric machinery. December 31

1887.

111 W. C. Quinby, London. An electrolyte and depolarising solution for voltaic batteries. Complete specification. January 4

114 W. A. Leipner, London. An improvement in dynamo-electric and electro-dynamic machines. January 4

171 H. C. Gover, London. Improvements in dynamo and other such-like machines. January 6

301 O. Zadig and E. Feldtmann, London. Treatment of refractory ores for the extraction of gold, silver, copper, or zinc, by thermo-hydro-electricity. January 8

305 O. Zadig and E. Feldtmann. Secondary electrical batteries. January 8

563 H. H. Leigh, London—From J. L. Clerc, France. An improved dynamo-electric machine. January 13

629 D. G. FitzGerald, London. Means for effecting the electro-chemical generation of chlorine in metallurgical operations for the extraction of gold and other metals from their ores. January 14

634 J. Hopkins, London. Electricity meters. January 15

700 S. Z. de Ferranti, London. Electric furnaces and apparatus for heating, lighting and carrying on chemical processes; and working such furnaces or apparatus. January 15

701 S. Z. de Ferranti. Electrical meters. January 15

702 S. Z. de Ferranti. Dynamo-electrical machines. January 15

717 W. B. Sayers, London. Disc dynamo-electric machines and motors. January 17

COMPLETE SPECIFICATIONS ACCEPTED.

1886.

2631 J. G. Johnson—From L. A. W. Desruelles. Electric batteries. December 24

2632 J. G. Johnson—From L. A. W. Desruelles. Treatment of materials used in electric batteries. December 21

2932 A. Schanschieff. Galvanic batteries. January 5

2956 M. Immisch. Electro-motors and dynamo machines. January 12

3476 A. Schanschieff and G. R. Fludder. Galvanic batteries. January 12

4057 P. Haddan—From J. Crosse. Voltaic piles and accumulators. January 19

7966 E. Commelin, G. Bailhache, C. Desmazures, A. L. de Bousignac. Improvements in secondary batteries acting as accumulators of electricity. December 31

12015 R. Eisenmann. Dynamo-electrolytic battery. January 8

12372 L. J. Crossley, W. T. Goolden and A. P. Trotter. Regulating the action of dynamo-electric machines. January 8

14352 J. Wodicka. Armatures for dynamo-electric machines. December 24

15988 W. Elmore, A. S. Elmore, and H. Barrett. Means and apparatus for extraction of metals from ores, especially from "bluestone" and similar complex ores; for refining copper, and manufacturing sulphuric acid electrolytically. December 31

XIX.—PAPER, PASTEBOARD, ETC.

APPLICATIONS.

1886.

17159 N. Browne, London—From J. Scherbel and T. Remus, Germany. Apparatus for drying strawboard, cardboard, and the like. Complete specification. December 31

1887.

117 A. M. Clark, London—From S. J. Depont, France. An improved manufacture of artificial ivory.

517 H. H. Lake, London—From E. R. Wiggin, United States. Manufacture of corrugated paper and similar fabrics or materials. Complete specification. January 12

523 H. H. Lake, London—From E. R. Wiggin. Machinery for use in the manufacture of corrugated paper and similar fabrics or materials. Complete specification. January 12

647 W. O. A. Lowe, Liverpool. Utilisation of a waste product, and manufacture of an improved antiseptic paper therefrom. January 15

COMPLETE SPECIFICATION ACCEPTED.

1886.

2915 J. C. W. Stanley. Preparation of materials suitable for paper making, and apparatus therefor. December 31

XXI.—EXPLOSIVES, MATCHES, ETC.

APPLICATIONS.

1886.

16868 T. T. Parkinson, Cheltenham, and C. V. Boys, London. Improvements in rockets and other fireworks. December 23

16888 J. T. Coles, London. An improvement in or connected with fusee vestas or wax matches for lighting cigars, pipes, etc. December 23

17035 J. Boag, Glasgow. The construction of blasting cartridges. December 29

1887.

272 H. E. Harris, London. Improvements in or connected with the manufacture of fusees, vesuvians, and the like. January 7

391 W. Bickford-Smith and G. J. Smith, London. Means of igniting fusees without exposing flame or sparks. January 10

393 W. Bickford-Smith and G. J. Smith. Means of igniting fusees without exposing flame or sparks. January 10

410 W. Walton, Sunderland. Method of, and apparatus for, lighting cigars, cigarettes, and pipes in wind or rain. January 11

448 E. Edwards, London—From R. Sjöberg, Sweden. A new or improved explosive. January 11

COMPLETE SPECIFICATIONS ACCEPTED.

1886.

758 W. D. Borland. Explosive substances, and absorbent materials therefor. January 19

3578 A. H. Durnford. Manufacture of gunpowder. December 31

3593 O. Bowen, A. S. Tomkins, and J. Cobeldick. Manufacture of gunpowder. December 31

8368 T. Johnston and G. Smith. Detonators or caps to be used with dynamite or other explosive. January 5

11137 W. Holmstrom, London. Machinery for applying igniting material to match sticks or splints. December 24

19079 C. R. E. Bell. Lighters for pipes, cigars, etc. January 12

UNCLASSIFIED.

17088 P. Ward and W. S. Oliver, London. Improvements in the manufacture and production of carbon. December 30

17140 A. Bessell and A. Bessell, London. Improvements in the process of purifying graphite. December 31

Printed and Published by EMMOTT & Co., New Bridge Street, Strangeways, Manchester, for the Society of Chemical Industry.

Non-Members 30/- per annum; Members 21/- per Set; Single Copies 2/6.

The Society of Chemical Industry.

COUNCIL FOR YEAR ENDING JULY, 1887.

THE JOURNAL.

NOTICES.

Notice is hereby given that the next Annual General Meeting will be held in Manchester in the month of July, 1887, instead of in Glasgow as originally arranged; the Annual General Meeting in Glasgow being postponed until 1888.

This change originated in a generally-expressed desire, resulting in a special invitation from the Manchester Section, supported by the cordial acquiescence of the Glasgow Section. It will enable members to visit both the Royal Jubilee Exhibition in Manchester, and the Glasgow Exhibition of 1888.

Full particulars as to the Manchester Meeting will appear in a subsequent issue.

The supply of copies of the Journal for January, 1882, and January, 1883, being now exhausted, the Secretary would be glad to receive communications from members possessing extra copies of those numbers, in good condition, with a view to purchase.

Should sufficient applications for complete sets be received, the numbers will be reprinted.

Authors of communications read before the Society or any of its Local Sections are requested to take notice that, under Bye-Law 43, they cannot receive the prescribed 50 copies of their communications unless they comply with the condition laid down in that Bye-Law—viz., that they give notice of their desire to receive such copies upon their manuscript before sending it to the Editor. Mention should also be made as to whether the Discussion is to be included in the reprint.

CHANGES OF ADDRESS.

H. E. Bunker, l/o Stocks Street; 21, Great Cheetham Street West, Lower Broughton, Manchester.

G. L. Cabot, l/o Cambridge; 82, Water Street, Boston, Mass., U.S.A.

C. F. Claus, jun., l/o Old Ford; 9, Nassington Road, Hampstead, N.W.

A. De Deken, l/o Cincinnati; 18, Rue Villette, Liège, Belgium.

C. S. Doggett, l/o Munich; Boston, Mass., U.S.A.

Jno. Dyson, l/o Cheetham; Derby Court, Long Millgate, Manchester.

C. D. Ekman, l/o London; Dieppe, France.

S. H. Emmens, l/o London; Silver Valley Railway Co., Thomasville, N.C., U.S.A.

A. Haacke, l/o Fenchurch Street; Kieselguhr Wharf, Gainsbro' Road, Hackney Wick, E.

Walter R. King, l/o Cannon Street; 22, Lawrence Pountney Lane, London, E.C.

H. A. Lawrance, l/o Harlesden; Brockweir, Grosvenor Road, Gunnersbury.

Jas. Lawrence, l/o Stevenston; 7, Bellgrove Terrace, Glasgow.

D. A. Louis, l/o Harpenden; 77, Shirland Gardens, London, W.

R. F. Macfarlane, l/o Cwm Avon; Grange Metal Works, Jarrow-on-Tyne.

E. G. Marks, l/o Unity Street; 38, Cornwallis Crescent, Clifton, Bristol.

N. H. J. Miller, l/o Regent's Park; Harpenden, near St. Albans.

Dr. Hugo Muller, Journals to 13, Park Square East, Regent's Park, N.W.

Jas. Murrie, l/o Gallowgate; 103, Bishop Street, Anderston, Glasgow.

J. A. Nichols, l/o Bankfield Terrace; Spring Bank, New Mills, near Stockport.

G. B. Nicoll, l/o Devonport; c/o Balfour, Guthrie & Co., Portland, Oregon, U.S.A.

J. H. Porter, l/o Tudor Street; 165, Queen Victoria Street, London, E.C.

Dr. A. Ree, l/o Leeds; 121, Manchester Road, Middleton, near Manchester.

T. Anderson Reid, l/o Weston; 11, Mersey View, Runcorn.

Jno. Robinson, l/o Farnworth; 5, Elizabeth Terrace, Ditton, Widnes.

A. Sansone, l/o Technical School; Vauxhall Chemical Works; and 8, Bignor Street, Cheetham Hill, Manchester.

A. H. Tuer, l/o Manchester; 28, Church Street, Standish, near Wigan.

P. G. W. Typke, l/o Cannon Street; 22, Lawrence Pountney Lane, London, E.C.

A. Wache, l/o Crepy; 6, Rue Lambrecht, Douai, France.

Thos. Warne, l/o Walsall; c/o Rainham Ferry Vitriol Co., Rainham, Essex.

J. D. Watson, l/o Whitehaven; Irtside, Holmrook, Carnforth.

C. J. Whittaker, l/o Plantation Street; Willow House, Accrington.

Chas. Wigg, l/o Runcorn; Hoole Bank, Chester.

W. Collingwood Williams, l/o 86; 68, Grove Street, Liverpool.

E. H. Winstone, l/o Bloomsbury Square; 2, Victoria Mansions, London, S.W.

CHANGE OF ADDRESS REQUIRED.

James Park, l/o Millburn Chemical Works, Glasgow.

LIST OF MEMBERS ELECTED, 2nd FEBRUARY, 1887.

R. H. Annison, 16, Water Lane, Tower Street, London, E.C., master lighterman.

J. F. L. Brunner, Trinity Hall, Cambridge, undergraduate.

W. A. Carlyle, The Elms, Yardley, Worcestershire, electrolytic engineer.

John Dickson, 16, Dale Street, South Side, Glasgow, oil merchant.

G. E. R. Ellis, 10, Colville Road, Bayswater, London, W., analytical chemist.

Upfield Green, Liebenheim, Clarendon Road, Watford, Herts., stationer.

R. A. Hadfield, Newhall Road, Attercliffe, Sheffield, steel founder.

Josef Hawliczek, 10, Bentley Road, Liverpool.

Wm. Scott Heriot, Pln. Leonora, Demerara, W.I., sugar factory engineer.

D. Lloyd Howard, City Mills, Stratford, London, E., chemical manufacturer.

Wm. Hume, 18, Lonsdale Terrace, Edinburgh, scientific instrument maker.

John Hunter, Minto House Medical School, Edinburgh, analytical chemist.

Jno. Laing, 38, Warrender Park Terrace, Edinburgh, chemical and oilworks manager.

Jno. McGlashan, Woodneuk, Gartcosh, near Glasgow, chemist.

W. G. McKellar, Eglinton Chemical Works, Irvine; N.B., analytical chemist.

J. G. McKinlay, 15, Charing Cross, Glasgow, student of chemistry.

T. E. Marshall, 4, East Castle Street, Merchiston, Edinburgh, student (science).

C. H. Master, Friary Brewery Co., Guildford, brewer.

Jno. Morison, Newbattle, Dalkeith, N.B., mining engineer.

Robt. Pinkney, 18, Bread Street Hill, London, E.C., manufacturing chemist.

Oliver Quibell, Highfield, Newark-on-Trent, manure manufacturer.

David E. Reid, Kaboonga Mines Co., Kilkivan, Maryborough, Queensland, smelter.

Thos. Robinson, 401, West Street, Glasgow, manager, Glasgow Alum and Ammonia Co. Limited.

A. Humboldt Sexton, 7, Sefton Terrace, Rutherglen, Glasgow, professor of chemistry.

G. M. P. Vary, 25, Grange Road, Edinburgh, science student.

Arthur J. Walker, 38, Portsdown Road, Maida Vale, London, N.W.

Alfred P. Wire, 1, Seaton Villas, Birkbeck Road, Leytonatono, schoolmaster.

RESIGNATIONS CANCELLED.

C. D. T. Bushill, Broom Hill, Great Barr, Birmingham.

Thos. Crawford, 10, Haldane Terrace, Newcastle-on-Tyne.

A. G. Jackson, The Willows, Martintown, Port Douglas, Queensland.

Wm. Kennedy, 28, Royal Exchange Square, Glasgow.

H. Meadows, Spa Place, Humberstone Road, Leicester.

V. de M. Mellin, The Polygon, Ardwick, Manchester.

Fred. H. Paul, c/o The Steel Co. of Scotland, 150, Hope Street, Glasgow.

Deaths.

G. T. Chinnery, Redheugh Chemical Works, Gateshead.

Astley P. Price, 47, Lincoln's Inn Fields, W.C.

J. M. Roberts, of Cornbrook Chemical Works, Manchester. —At Southport, February 18.

London Section.

CHEMICAL SOCIETY'S ROOMS, BURLINGTON HOUSE.

Chairman: David Howard.

Committee:

Sir F. A. Abel.
H. E. Armstrong.
W. Lant Carpenter.
W. Crowder.
C. Graham.
S. Hall.
A. K. Huntington.
R. Messel.
R. E. R. Newlands.
B. Redwood.
T. Royle.
John Spiller.
G. C. Trewby.
J. Williams.

Hon. Local Sec. and Treasurer: Thos. Tyrer, Garden Wharf, Church Road, Battersea, S.W.

The meetings of the London Section will be held on the first Monday in each month.

SESSION 1886—87.

Prospective Arrangements.

March 7.—Messrs. Cross and Bevan, "Mr. Hermite's Method of Electrolytic Bleaching."
„ Mr. J. Mactear, "The Castner Process for Production of Sodium."
„ "A New Method of Elevating Liquids, specially applicable to Acids."
April 4.—Triennial Election of Sectional Officers and Committee.
„ Discussion on Papers read 7th March.
„ Dr. J. M. H. Munro, "Further Notes and Experiments on the Composition and Manurial Value of Filter-pressed Sewage Sludge."

Notices of Meetings and Papers will be found in the Scientific Journals.

Notices of papers and communications to be made to the Local Secretary.

ON THE VARIOUS FORMS OF FILTER PUMPS OR WATER-JET ASPIRATORS.

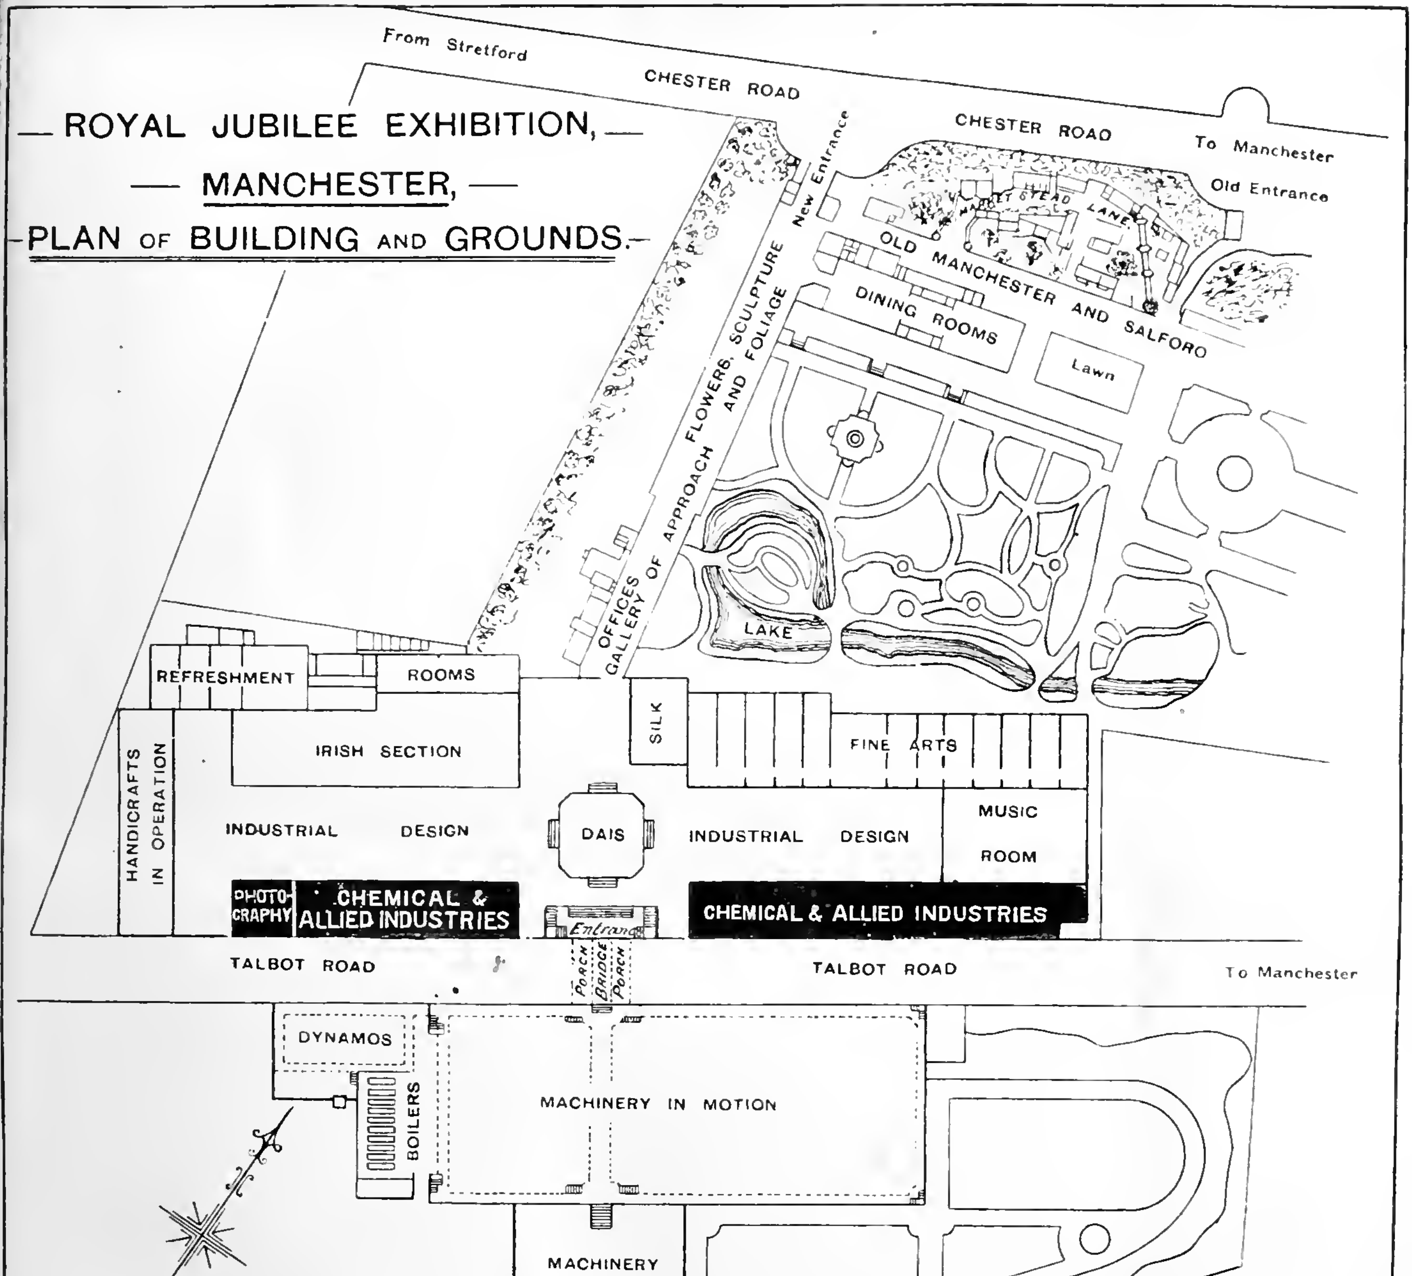
BY T. FAIRLEY, F.R.S.E., F.I.C.

Since the publication of Sprengel's paper on the vacuum in 1865, and Bunsen's paper on an improved mode of filtration in 1868—69, the applications of the air pump have become so familiar as to be considered almost indispensable in chemical and physical laboratories.

As commonly understood, the air pump and the aspirator are machines which differ not in principle, but only in degree, and Geissler, Joule, and others have constructed mercurial aspirators which are air pumps capable of giving very perfect vacua.

The pumps used in chemical and physical laboratories may be classified as follows:—

1. Barometric or weight pumps, which are: (*a*) *Statical*, such as the Geissler, which exhaust air by the alternate emptying and filling of a vessel forming the upper part of a barometric column. (*b*) *Dynamic*, such as the Sprengel, in which the continuous falling of a liquid through a tube of uniform



A Ground Plan of the Royal Jubilee Exhibition of Manchester is herewith inserted, and shows the position of Section III. (Chemical and Allied Industries). Space has been allotted to applicants as far as the area available will allow.

bore and of a length rather greater than the barometric column of the liquid produces the exhaustive effect. The barometric pumps are generally worked by mercury or water.

2. Momentum or pulsation pumps, such as the Jagn pump, which depend on the momentum and pull of an intermittently interrupted column of the liquid used, the action being similar to that of the hydraulic ram used for lifting water by the suddenly interrupted flow of a larger quantity of water. In the ram the water is raised in front by the momentum; in the Jagn pump air is pulled in behind.

3. Injector or pressure pumps, which depend on the laws relating to the flow of fluids (either gases or liquids) through an expanding mouth-piece. In laboratories they are generally worked by water, but they may be worked almost equally well by any gas or liquid under pressure, and acting in any position downward, horizontal, or even upward. They are identical in principle, and nearly so in construction, with the injector water pump described by Professor J. Thomson in 1852 for raising water, or with the steam injector patented by Giffard for feeding steam boilers.

The injector pumps are the most numerous of those employed in laboratories, and they are adapted either to work with a small quantity of water at high pressure, or with a larger quantity at low pressure.

The following is a brief statement of the history of the subject:—

1. *The Barometric or Weight Pump:—*

(*a*) *Statical.*—Toricellian vacuum discovered, 1643.

1722. Description, by Swedenborg, of a barometer pump.

1847. Patent for application of the barometric column in the working of vacuum pans in sugar refineries, granted to J. Johnstone.

1855—58. Geissler introduced and used his mercurial barometric pump, which has been modified and adapted for various purposes.

1862. Improved by Töpler, *Dingl. Poly. Jour.* 1862, p. 426; 1865, by Poggendorff, *Ann.* cxxv. p. 151; 1865, by Jolly; 1873, by Mitscherlich, *Pogg. Ann.* cl. p. 420; 1881, Bessei-Hagen, *Wiedemanns. Ann.* xii. p. 425; also by Dittmar (Challenger Reports), 1882; F. Neisen, *Zeitsch. f. Instrumentenkunde*, 1882, p. 285.

1885. Improved pump patented in Germany, by Albert Geissler, D.R.P., 32,224. Modifications of the statical pump have also been described by Pflüger, Weinhold, Lane Fox, Joule, and many others.

(*b*) *Dynamic.*—The trompe or water air blast used from time immemorial.

1852. G. S. Johnson described an aspirator for use in laboratories worked by a constant stream of water, *Chem. Soc. Qu. Jour.* 1852, p. 186.

1865. Sprengel published his researches on the vacuum and described his pumps worked by mercury or other liquids, *Jour. Chem. Soc.* 1865, p. 9.

1868. Bunsen described pump and apparatus for quickened filtration and other purposes, *Ann. der Chem. u. Pharm.*, Bd. 148, p. 277. Modifications of the Sprengel pump or parts of it have also been described by McLeod, Swan and Stearn, Gimingham, Weinhold, St. Claire Deville, and many others.

2. *The Momentum or Pulsation Pump:—*

1872. Jagn described his pump which he had used for about two years before that time, *Pogg. Ann. der Phys. u. Chemie.* 148, p. 317.

1873. Mendelejeff on the "Pulsir pump," *Annalen der Chem. u. Pharm.* 165, p. 63—91.

1872. Thorpe on a modification of the Jagn pump, *Phil. Mag.* 1872, p. 249.

1873. Foote on a modification of the Jagn pump, *Amer. Jour. Science and Arts*, 1873, p. 361.

1876. Linneman on a practical form of water air pump, *Annalen der Chem. u. Pharm.* Bd. 176, p. 327; 177, p. 295.

1886. O. Witt on a simple air pump, etc., *Chem. Zeit.* 10. 760: also this Journal, Sep. 1886, p. 503.

1886. A. Bornträger on same, *Ber.* 19, 1690.

3. *Injector or Pressure Pumps:—*

1719. Hawksbee, one of the improvers of the common brass air pump, found that on blowing through a tube into a small box, the air escaping by another tube opposite the first, the pressure of air in the box became less than that of the atmosphere, and not greater. Fig. 1.

1738. Daniel Bernouilli discovered that water passing from the narrow to the wide end of a conical tube could draw into its current water from another vessel at a lower level. Fig. 2.

1801. Eytelwein published his "Handbuch der Mechanik und der Hydraulic," in which he described many original experiments and investigated the laws relating to the discharge of water from variously-shaped outflow tubes.

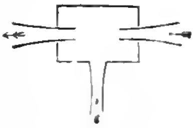

FIG. 1.

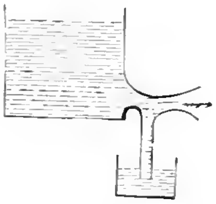

FIG. 2.

1830—50. The steam-jet aspirator used in ventilating mines, patented by S. Carson in 1840. Also used by G. Stephenson in improving the draught of the locomotive.

1852. Prof. James Thomson described a jet pump for lifting water (*Brit. Ass. Reports*, 1852—53), and found that it utilised about one-fifth (0·18) of the power due to the falling water. Through A (Fig. 3) water descends from a height, passes through the jet C, and comes out at B, drawing up with it water from D.

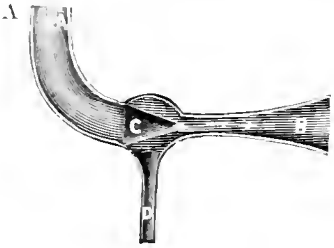

FIG. 3.

1855. Clement Desormes (*Ann. de Chem. et de Phys.*, 36, p. 39), showed that a plate of metal or wood brought near an orifice in the side of a reservoir of compressed air will, after the first repulsive action of the current, be attracted; and will remain rapidly oscillating within a short distance of the opening.

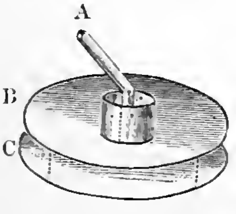

FIG. 4.

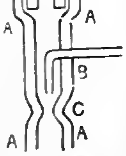

FIG. 4*a*.

This experiment may be demonstrated by blowing between the fingers against a piece of paper, or by two circular cards mounted as in Fig. 4, as described in Weinhold's "Physics," p. 315. On blowing through the tube A (Fig. 4), the card C, which is hung from the card B by three small threads, is drawn up and attracted towards B. This, like each of the preceding experiments, is a case of the passage of a fluid through an expanding mouthpiece, causing a diminished pressure as compared with that in front, which in each case is that of the atmosphere.

1855. C. F. Delabarre patented a steam pump for lifting water, ventilating mines, etc.

1858. Giffard patented his injector for feeding steam and other boilers, of which numerous modifications have been described and patented.

1872. Christiansen described the first water air pump on the injector principle, Fig. 4*a*. A is a piece of thick-walled indiarubber tubing which has been perforated at B by a hot wire and constricted at C by a small ring fitted over the tube. On inserting at B a short piece of bent glass tubing drawn out to a jet, and connecting the top end of A with the water supply under moderate pressure, air is drawn in through the bent tube and a considerable vacuum obtained.

1874. J. Lovett described an improved filter pump, *Chem. News*, May 15, 1874, p. 209.

1874—75. P. Casamajor on "Implements of Filtration," described a filter pump in the *American Chemist*, April, 1874, and *Chem. News*, June 27, 1875, p. 33.

1875—76.—Injector air-pumps were introduced and used by dentists at, or prior to, this date. Fisk's "Automatic Saliva Ejector" is described, and figured in an American price list of 1876.

Injector air pumps worked by steam have also been proposed for laboratory use by Lovett, Kochinke, Teclu, and others.

1875. Arzberger and Zulkowsky described the first form of their pump, *Ann. der Chem. u. Pharm.* Bd. 176, p. 327.

The dates and references to the other pumps are each given where known, with the table of tests relating to the pump.

The pumps which are now most frequently used in laboratories are those of the injector class. As certain errors are found in text-books regarding fluid motion in injectors, a few additional experiments may be quoted.

Mr. W. Froude, in his address to the Mechanical Section of the British Association at Bristol in 1875, showed that water under any head H, Fig. 5, passing through a contracted pipe, does not exert an excess of pressure on the converging surface which it meets (as is commonly supposed), but that the pressure is least at the contracted part, as shown by the levels in the gauge-glasses *a*, *b*, *c*, *d*, *e*. Further, he showed that if the pipe be much contracted the pressure can be still further reduced; so that if we have two cisterns A and B connected by such a contracted pipe, a portion of the pipe as at C, Fig. 6, may be removed without the flow of the liquid from A to B being interfered with; the water rising in the cistern B to within a slight distance of its level in A. At F, in the central line of the connecting pipe, the full head of pressure *h* is exerted, but there is practically no movement, while at C there is no pressure, but very rapid movement; and on trial it is found that the pressure and velocity of movement being convertible and complementary, the pressure at any point varies according to the square of the velocity at that point. In any given case the pressure observed, plus that which has been lost in producing velocity, is constant, and equal to the total head of water *h*, Figs. 5, 6, 7. If we modify Mr. Froude's experiment and cut off the pipe at E, Figs. 6, 7, the pressure at E is then simply the general pressure of the atmosphere, and the whole of the pressure due to the head of water in A has been changed into velocity; but the velocity at C must be greater than the velocity at E by as many times as the sectional area of the pipe at C is contained in its area at E. The velocity at C being so much greater than at E, the pressure must be less, and therefore less than that of the atmosphere. The tube G may be regarded as a gauge to show the minus pressure, and, if this gauge be supplied with mercury, the latter

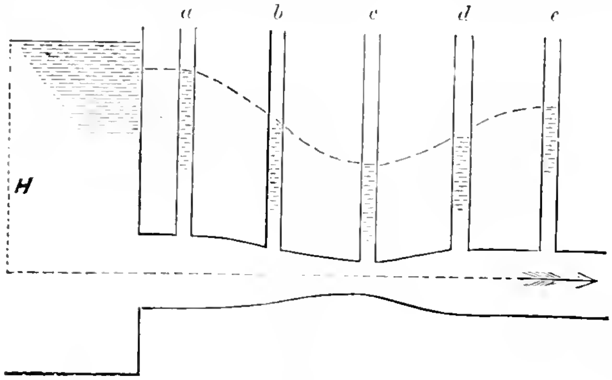

FIG. 5.

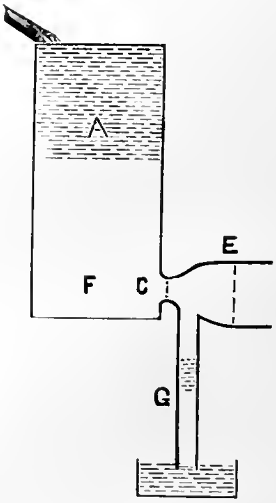

FIG. 7.

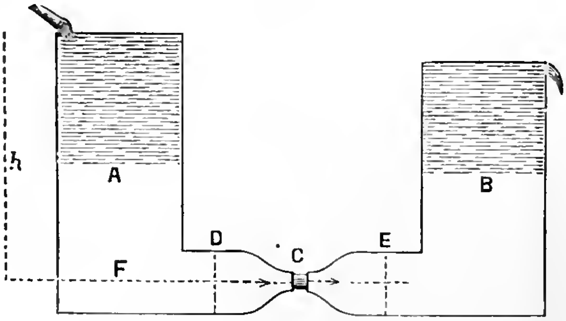

FIG. 6.

will, under favourable conditions, rise to near the height of the barometer.

In place of a head of water or other liquid, one may also use air, steam, or any gas under pressure, to obtain similar results, and with air or steam under high pressure, working one of these injector pumps, a good vacuum may be obtained.

On examining the various pumps of this class which have been invented, we find that in some, Figs. 11, 12, 14, 16, etc., the water enters by a jet placed immediately over a constricted tube, the narrowest part of which may be called the neck. I have measured the areas of the jet and of the neck in a considerable number of pumps from different sources, and find that the area of the neck is generally about twice that of the jet; or the diameter of the jet is to that of the neck as 1 : $\sqrt{2}$ or 1 : 1·4. This proportion differs somewhat from that given by Arzberger and Zulkowsky—viz., 1 : 1·22, but though the mathematical formulæ employed by these authors appear to me to be correct, yet the number of experiments quoted in the paper are far too few to *establish* the above ratio; and on applying more recent experiments to the same formulæ a ratio of the two diameters approximating to that of 1 : 1·4 is obtained. It, therefore, appears that in many cases the makers of these pumps have by trial or accident made use of dimensions which come near to those required by theory.

By taking the working part of an ordinary Sprengel pump as arranged by Bunsen, one can place within the upper part of the fall tube, close to the jet a smaller tube constricted in its upper part to form a neck, and projecting below a little beyond the Bunsen tube, so that the two can be connected air-tight by means of an indiarubber tube stretched and tied over both. By this means one obtains a very efficient injector pump, in which one can, by using neck-pieces more or less constricted, study the best working proportions. My experiments carried out in this manner point to the ratio of diameters of jet and neck 1 : 1·4 as probably the best.

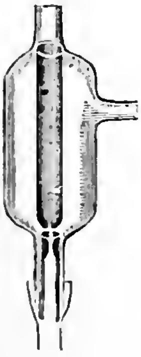

Fig. 8.

In this form of pump, Figs. 11, 12, 14, 16, 17, 18, 19, 20, 24, and 26, the air is drawn in all round the jet as it enters the neck and expanding mouthpiece; but the air may be drawn in on one side only, as in Figs. 21 and 22, or the air may be drawn in by a central tube, in which case the water fills the body of the pump, as in Figs. 13, 15, 23, 27, and 28. These variations make no difference whatever in the principle or working of the pump, but with the last-mentioned form—Fig. 13, made of brass to unscrew—one can insert in the neck small tubes of different sizes, and so alter the working of the pump. Generally, the smaller the neck the higher the pressure required to produce any given degree of exhaustion; and the wider the neck, up to a certain limit, the less the pressure. On the other hand, those pumps which work with low pressures require very much more water than those working with high pressures. On multiplying the weight of water used per minute by its head or pressure in feet, we obtain, in foot pounds (marked F. P. in the tables), the power required to produce the exhaustive effect in one minute's working of the pump. Compared in this manner, the low pressure pumps are much less efficient machines than the pumps working at higher pressures.

The pumps, Figs. 11, 12, and 15, have a trap at the bottom serving to break the continuity of the water current, and so avoid a kind of setting of water and air in particular parts of the outflow tube. by which the efficiency of the instrument might possibly be slightly diminished. In others the same effect is sought by bending the tubes, as in Geissler's, Fig. 19, or Bulk's, with the tube bent at right angles.

It is important to have the water supply much in excess of that required by the pump used. On turning the water tap full on, it should supply in one minute a quantity of water two to three times the maximum quantity required by the pump in the same time. Neglect of this point has led to some pumps being condemned unjustly.

The apparatus used in testing the various pumps is shown in Fig. 9, excepting that with the pumps requiring much water, larger water pipes had to be used. A is the flexible water-supply pipe, formed of sound rubber tubing, covered with a double thickness of strong canvas sewn over it. B is a strong iron bottle capable of standing any pressure up to or over 100 pounds per square inch, and having one tube going to the bottom, passing through the neck, and joining the water pipe by a T-piece. For the purpose required the larger this bottle is the better, but a good sound iron mercury bottle may be used. The bottle B being air tight and water-tight under pressure, and being also full of air when connected with the water pipe, the air cannot escape, but is compressed by the pressure of the water. At a pressure double that of the atmosphere the air will be compressed to one-half its volume (say at 15 pounds pressure), and the bottle will be half full of water; at 30 pounds pressure the bottle will be two-thirds full of water. Thus, when the water pressure varies, as it frequently does, in towns where there is much demand on the service, the bottle B, by its reserve of water under pressure, helps to keep the supply of water to the pump more constant, and may be said to act as a governor. The water taps, where there is a high water pressure, are generally plug taps, which do not permit the pressure from the bottle B to go back into the water main.

The glass tube C (connected by a T-piece with the water pipe) serves as a manometer, and contains within it a small tube, 30in. long, closed at the upper end, and dipping in mercury. This small tube is full of air, which by its compression, read off on the barometer scale adjacent, indicates the water pressure. D is a Bourdon's pressure gauge for the same purpose, which was used more especially when wider water tubes had to be employed. At *a* is a tap which, on closing it, shows the pressure on the closed pipes. I is a Geissler pump placed so as to show the working of the apparatus. J is the water outflow tube. The pump is connected, through the safety tube F, with the barometric gauge E, and with the receiver to be exhausted—which is the bottle H—having a capacity of 2·2 litres, and provided with a special tap similar to that at the bottom of the safety tube F (see Fig. 10). By turning these taps, either air can be admitted or the connection can be shut off. The safety tube F has a Bunsen valve fitted inside to the end of the tube G. To work the apparatus the water is turned on to the pressure required, the tap on the bottle H is turned to connect with the pump, and the tap at the bottom of F is turned open to the air. All being ready, this latter tap is turned round to shut off air and connect with the receiver H, at the same instant that the minute clock K is started. The clock K has a fly back action, and strikes the minutes, so that the observer can read off the barometric gauge E as each minute is struck, and record the results. After ten minutes, the tightness of the connections is tested by shutting off first the pump and then the bottle; and if the gauge E remains at a constant level, or so that the fall is within 1mm. in five minutes, the readings are accepted as approximately accurate. Part of the connections can also be tested separately by closing the tap *b*; and on then working the pump only F and the gauge E are exhausted, which, with a good pump, attains its limit within a minute. The absence of air bubbles when the end of the outflow tube dips in water shows that the connections between *b* and the pump I are air-tight.*

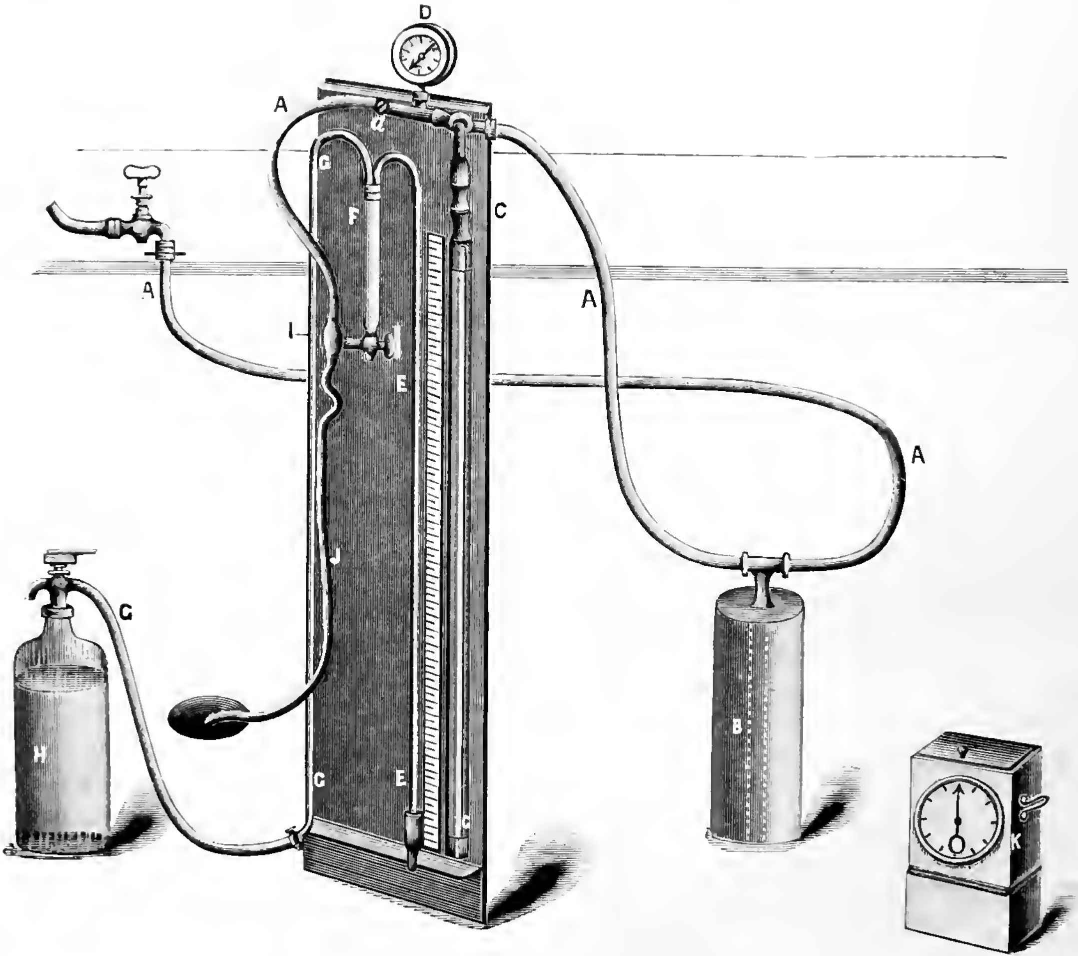

Fig. 9.

The above apparatus can be worked by one person, but it is more convenient to have two—one to watch the clock and give an eye to the water-pressure gauge, the other to watch the barometric gauge, and, if necessary, to keep his hand on the water-supply tap in case of fluctuations of pressure.

Fig. 10 shows the tap in full size which is fitted in various parts of the apparatus. It is made from an ordinary good gas tap, which should be specially ground, as they are never air-tight when sold. The little screw and washer at the bottom of the plug are first removed, and a hole bored from C into the ordinary through hole of the tap, which is then closed by solder on one side at D; then trimmed and reground, so that the hole in the plug is from the bottom to one side only. A short piece of tubing, F F, is then soldered on to the body of the tap as shown, and a pointer E soldered on the top of the plug to point which way it is open. When the plug is turned across in the ordinary position of a closed tap it is closed to both A and B; when the pointer points towards A it opens towards A, and if towards B to B. The tube F F is fitted air tight by means of a stopper in the bottle H (Fig. 9).

It is by means of these taps, which I devised about three years ago, that during that time one pump has been utilised to do all the exhaustion work of my laboratory. The pump is connected with a main pipe passing along the laboratory tables, and at each worker's place is a bottle similar to H (Fig. 9), which

---

* To obtain the requisite tightness of taps and connections, I have found a lute, made by heating indiarubber with a small proportion of vaseline, of great service. The vaseline is melted over a very small burner in a porcelain basin, and the rubber (preferably good black rubber, though it may be old rubber that has lost its quality) added in small portions as it dissolves in the vaseline. The basin may be covered with a glass plate, and the slow heat used should cause scarcely any distillation of volatile products from the rubber. The lute I have used contained about 10 per cent. of vaseline to 90 per cent. of rubber.

is fixed below the table: the neck of the bottle, or better, the tube F F (Fig. 10), rising above the table. One end of the tap (say B) is connected with the vacuum main pipe by soldered lead tubing; the other end of the tap A is connected by a flexible tube with any filtering apparatus or other vessel to be exhausted.

In using this arrangement, it will be observed that all the vacuum supplied at A must come from the bottle below F F, and not from the main pipe, which is then shut off. When the vacuum is not required at A, the tap is turned round towards B, to raise the degree of exhaustion in the bottle. As there are a number of such bottles in the laboratory, they form together a vacuum reservoir of some capacity, available at once without waiting. If well fitted, the taps retain the vacuum for several days.

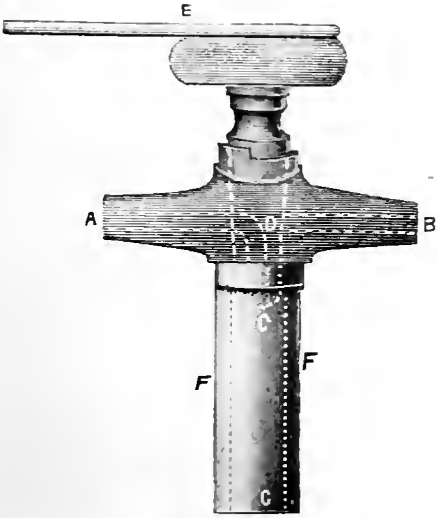

Fig. 10.

Explanation of the Tables.

In the tables which follow, the column below P. indicates the water pressure in pounds per square inch; F.P. is the product of the weight of the water used in pounds multiplied by its fall in feet; or, what is the same, its "head" in feet; F.P. therefore means ordinary foot pounds of power or energy spent in working the pump. The other columns give the readings of the barometric gauge in mm. of mercury during the successive minutes' working of the pump up to ten minutes. Thus, the pump shown in Fig. 11 gives, at ten pounds water pressure, after one minute's working, a vacuum, in receiver bottle H (Fig. 9), of 2·2 litres capacity, equal to 302mm. of mercury; and after ten minutes' working of the pump, a vacuum equal to 702mm. of mercury. The last column to the right states the quantity of water used per minute in litres.

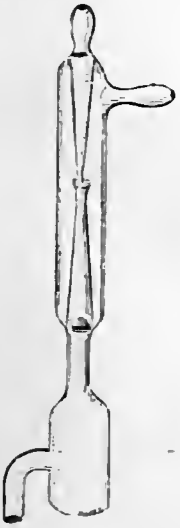

Fig. 11.

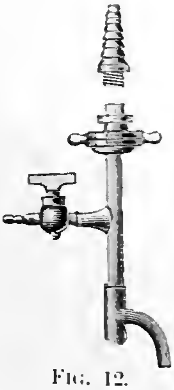

Fig. 12.

The results given are corrected to a common barometric column of about 760mm., and may therefore be compared with one another. Sometimes there is air in the water pipes, which introduces an error into these time tests; but the irregularity so introduced is generally noticeable, and is eliminated by repeating the tests. The greater number of the tests have been repeated several times.

The first minute's working gives, in my opinion, a fair test of the practical usefulness of the pump; and during the first minute the influence of slight possible leaks or imperfections in the testing apparatus is at a minimum.

The following factors may be useful:—

Pounds per square inch multiplied by 2·31 equal feet head of water.
Pounds per square inch divided by 14·7 equal atmospheres.
Pounds per square inch multiplied by 0·0703077 equal kilogrammes per square centimetre.
Pounds per square inch multiplied by 51·7 equal millimetres column of mercury.
Foot pounds multiplied by 0·138 equal kilogrammetres.

Used as a blower, this pump blows 5·6 litres of air per minute at 40 pounds pressure; or about a cubic foot of air in five minutes.

Best Results First Minute.—The results obtained from 20 to 40 pounds pressure are all good, but that at 20 pounds pressure is the best. As regards power, the best result is at ten pounds pressure.

The above pump was obtained direct from Messrs. Alvergniat; but another, obtained through Messrs. Townson & Mercer, of London, gave almost identically the same results.

* Alvergniat Frères, 10, Rue de la Sorbonne, Paris.

Used as a blower, this pump blows, at 40 pounds pressure, 4·35 litres of air per minute; or a cubic foot of air in 6·5 minutes.

Best Results First Minute.—As regards quantity of water used, this pump gives nearly equally good results at 20, 25, 30, 35, and 40 pounds pressure; but the result obtained at 20 pounds pressure is slightly in advance of the others. As regards power used, the best result is at the lowest pressure—10 pounds.

Used as a blower this pump blows in one minute 4·363 litres of air at 25 pounds pressure; or a cubic foot in 6·5 minutes.

* *Best Results First Minute.*—For quantity of water at 5 and 7 pounds pressure; for power at 5 pounds pressure.

Th. Schorer, in 1878 (*Zeitsch. f. Anal. Chemie*, 1878, p. 177), describes a low pressure pump, which he claims was shown in 1873, in the Chemical and Physical Section of the German Association for the Advancement of Science.

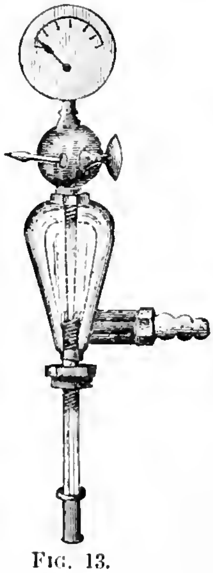

Fig. 13.

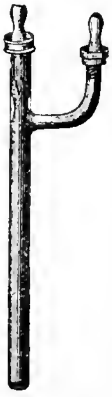

Fig. 14.

Fig. 15.

At 15 pounds pressure the author states that his pump requires 20 litres of water per minute. As ordinary water-pipe fittings do not often supply this quantity of water, I have not tested Schorer's pump. It is a pump adapted for very low pressures, ranging from 2 to 15 pounds, and using from about 10 to 20 litres of water per minute.

40	866	458	595	660	697	715	725	731	735	733	741 ,,	4·26 ,,

Used as a blower, this pump blows, at 40 pounds pressure, 2·65 litres of air per minute; or a cubic foot of air in 10·6 minutes.

Best Results First Minute.—For quantity of water at 30 pounds pressure; for power at lowest pressure.

Another pump of this pattern, from a different source, gave from 10 to 20mm. lower results. The position of the jet, and the proportions of the jet and constriction, are here very important. A Bulk's pump obtained from Vienna with bent tube at bottom (instead of the hole at the side, as described in the author's paper) gave very unsatisfactory results, and appeared to be out of proportion.

Fig. 16.

---

* The bottom outflow tube being adjustable, this pump may, with a very large water supply, give quicker evacuations than the above. On the other hand, by screwing up the bottom tube to its utmost limit, this pump assumes a high-pressure character, and then works up to 40 pounds pressure, using much less water. See Tables A and B.

Fig. 16.—FINKENER'S GLASS PUMP.

Winkler's Industrie Gaze, I. p. 23.

35	1466	582	697	728	741	745	747	—	—	—	—	,,	8·21	,,

Used as a blower this pump blows 6·38 litres of air per minute, at 35 pounds pressure; or about a cubic foot of air in 4·4 minutes. At lower pressures than 25 pounds the pump works only very slowly, but using the gauge only without the receiver, the gauge rises to 260, 396, 515, 671 and 733mm., at pounds pressure 10, 15, 20, 25 and 30 respectively.

40	459	421	535	598	612	673	697	710	723	731	736	,,	2·26	,,

Used as a blower this pump at 40 pounds pressure blows 3·24 litres of air per minute; or a cubic foot in 8·7 minutes.

Best Results First Minute.—For quantity of water at 40 pounds pressure; for power at 10 pounds pressure.

This is a high-pressure pump with very small holes, and for the quantity of water used it is very efficient. When received from the makers this pump was fitted with washers of lead, which were not perfectly tight, especially at the higher vacua. The above results were obtained after inserting well greased leather washers in place of those of lead.

FISCHER'S BRASS PUMP.

(Made by DESAGA, of Heidelberg.*)

P.	F.P.	Minutes Exhausted.											Quantity of Water used per minute.	
		1	2	3	4	5	6	7	8	9	10			
10	89	226	294	315	320	—	—	—	—	—	—	mm.	1·76	litres.

40	773	491	606	671	707	720	729	735	741	743	747	,,	3·80	,,

Used as a blower, this pump blows, at 40 pounds pressure, 4·7 litres of air per minute; or a cubic foot in 6 minutes.

Best Results First Minute.—For quantity of water used at 40 pounds pressure; for power used at 20 pounds pressure.

This pump is of similar construction to that from Dreyer Rosenkranz and Droop, of Hannover, but it has wider holes and uses more water.

Another brass copy of the Hannover pump is also frequently met with in this country. One that I have tested from G. Mason & Co., of Glasgow, after slightly widening the hole and neck, used from 1·3 to 2·8 litres of water at the above pressures, and gave exhaustions in very nearly the same proportions as the above, but rather better for the quantity of water used.

FIG. 19.

* Lent by Dr. Knecht.

Used as a blower, this pump blows 3 litres of air per minute at 40 pounds pressure; or a cubic foot of air in 9 minutes.

Best Results First Minute.—For quantity of water at 35 and 40 pounds pressure; for power at 10 pounds pressure.

One of these glass pumps has been in common use in my laboratory since 1883, doing all the exhaustion work required. It still works as well as when first put up. The average water pressure at the laboratory is from 50 to 60 pounds in the closed pipes, so that 35 pounds can generally be obtained while the pump is working.

Fig. 23.

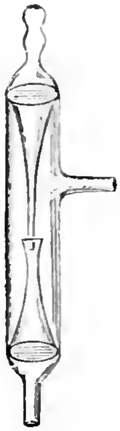

Fig. 24.

Fig. 23.—MAWSON AND SWAN'S GLASS PUMP, No. 2.

(Sent out about 1877—78.)

Used as a blower, this pump blows at 40 pounds pressure 4 litres of air per minute; or a cubic foot of air in 7 minutes.

Best Results First Minute.—For quantity of water at 40 pounds pressure; for power at 20 pounds pressure.

A great many experiments were made to obtain the best position by raising or lowering the bottom part of the pump. The above results are the best obtained.

Used as a blower, this pump blows at 20 pounds pressure 2·76 litres of air per minute; or a cubic foot of air in 10 minutes.

Best Results First Minute.—For quantity of water at 15 and 20 pounds pressure; and for power at the lowest pressure.

Tables A (p. 75) and B (p. 76) are summaries from the preceding, with ratios calculated between the air blown or pumped out and the water used.

Table A shows results, with the pumps used as blowers, which may be also regarded as exhaustions, with a receiver of infinitely large capacity, or as the rate of exhaustion at the *exact instant of starting the pump* with any receiver of ordinary limited capacity. The rate of exhaustion varies as the exhaustion proceeds, but the first minute's working gives a useful result for most practical purposes. In the preceding tables given with each pump the exact capacity of the receiver and tubes exhausted was 2·28 litres, and Table B gives the results of the *first minute's working* with each pump, at various pressures, stated as before. On multiplying these readings of the mercury gauge by the factor 0·03, we obtain the volume of air pumped out in litres, from which the ratios of air and water volumes in the right hand column are calculated; also on dividing the readings by 760, or multiplying by 0·0013, we obtain the volume of air extracted, compared with that of the receiver taken as unity.

Besides the pumps named in the preceding tables I have also tested some others, including the Jagn and the Witt pulsation pumps. The latter are slower in their action than the injectors, as they do not work continuously like them.

The results given in the tables enable any one knowing the average pressure and quantity of water available in his laboratory to select the pump which will give either the quickest evacuation or the highest result in proportion to the quantity of water used.

Some, such as those of Alvergniat, Finkener, Körting, and Arsberger and Zulkowsky, give very high results at their maximum pressure, but use considerable quantities of water. Others give excellent results in proportion to the water used, such as those of Bulk, Fischer, Knecht, the small No. 3 Mawson and Swan pump, and the small brass pump of Muencke.

As mechanical machines doing duty for the energy supplied to them none of these instruments are very perfect; but the best in this respect are the pumps of Fischer, Körting, and the Muencke glass pump, each worked at the lowest pressures.

I have to thank many of the makers and dealers in apparatus for catalogues and information courteously supplied. Besides nearly all the firms in this country, many of whom have taken much trouble in the matter, I have also to thank the foreign firms, some of whose names are given under the various pumps. Professor A. Weinhold, of Chemnitz, kindly gave me some notes and references, and Professor Hummel and Dr. Knecht lent the pumps mentioned in the tables.

DISCUSSION.

The Chairman regarded Mr. Fairley's account of these various pumps, and his explanation of their action, as most lucid. Dr. Sprengel had revolutionised our ideas of physics by what was still known as the "Sprengel" pump, and since then great advances had been made in the construction and application of these apparatus. Considering how extremely convenient they had been found for laboratory purposes, he was surprised that they were not universally adopted, and that people should still be found with patience sufficient to endure the old class of apparatus. He looked forward with much interest to the appearance in the Journal of Mr. Fairley's details, because of their eminent thoroughness and clearness.

Mr. J. W. Leather said he would like to know whether Mr. Fairley had ever tried the experiment of a number of persons using the same filter-pump. It seemed to him that the thing might be practicable where a number of students were working together and only a small pressure was required—provided the pipes did not leak. But considering the number of joints that would be required and the generally defective condition of rubber tubing, he feared the joints would be found to leak rapidly. He certainly would not like to try it except as an experiment. The question might become serious if one person wanted to use the pump for working an apparatus for distillation in vacuô, or at a very low pressure—say about 10 millimetres—and another happened to be working the same pump with only a paper filter.

The Chairman said he had found by experience that with an ordinary Körting pump it was possible to have 15 branches at work simultaneously. Under such circumstances, no difficulty had been found in getting a pressure of half an atmosphere in each branch, notwithstanding that ordinary tubing and ordinary gas-cocks were used. He therefore thought no difficulty need arise in dividing a vacuum.

Mr. Leather replied that that was no doubt quite true; but what he wanted to point out particularly was the fact that the practice of distillation in vacuô was a common thing now, and it was absolutely necessary in manipulating some organic substances to distil under a pressure of about 10 or 15 millimetres only. He feared that under such circumstances the practice suggested by Mr. Fairley might have awkward results.

The Chairman invited Mr. Fairley to state to the meeting what his experience of such distillation had been.

Mr. Fairley was sorry to say he had not had much experience in the use of the air pump for the purpose of distillation in vacuô. But as regarded joints, tubes, taps, and so on, he had had considerable experience, and he was satisfied that it was possible to make and keep any ordinary gas-taps air-tight. The rubber tubing which he preferred was the kind used by photographers for working pneumatic shutters, which was quite strong enough to resist atmospheric pressure.

ENGLISH-GROWN TOBACCO.

BY ARTHUR WINGHAM.

I DESIRE to introduce to the notice of chemists the results of a few analyses and experiments in connection with what may probably become a new industry in this country—viz., tobacco-growing. It is a subject which is being seriously discussed, and in which a great amount of public and scientific interest is being shown. The results obtained and here recorded are purely of a scientific nature, and tend to throw considerable light on the subject, as far as they go, and have been obtained by experimenting on some samples of English tobacco grown by Lord Harris at Faversham. The work has been carried on in the Chemical Laboratory of the Royal School of Mines and Normal School of Science.

The English samples examined were of four distinct varieties, and were consequently arranged into four lots, which were numbered 1, 2, 3, 4, and examined separately. The following table shows the average measurements and weights of leaves :—

	Length.	Breadth at broadest part.	Weight.
No. 1.	22 inches	14 inches	12·0 grammes
,, 2.	16 ,,	9 ,,	5·4 ,,
,, 3.	20 ,,	7 ,,	9·7 ,,
,, 4.	20 ,,	9 ,,	8·3 ,,

No. 1 was of a uniform moderately-deep dull-brown colour. Rather thick and tough.

No. 2 was of a light brown colour, partly green, and thin and somewhat slender.

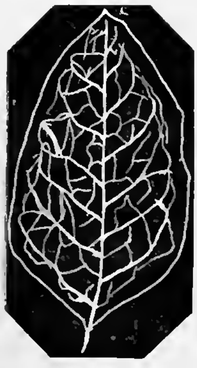

FIG. 1.

FIG. 2.

No. 3 was deeper in colour than No. 1. Thicker also and tougher.

No. 4 was somewhat similar in shape to No. 1, but lighter colour and thinner, although moderately tough.

All the leaves were damp and unfermented.

Before experimenting with them they were dried at 100° C. until no further loss in weight took place.

PERCENTAGE OF WATER.

No. 1	21	No. 3	22
„ 2	26	„ 4	20

For the purposes of comparison some samples of foreign tobacco were taken, and worked side by side with the English samples, and it would be as well to introduce them here. Unfortunately, these were all fermented leaves, it being impossible to obtain any that had not undergone fermentation. These samples were three in number, and were numbered 5, 6, and 7.

FIG. 3.

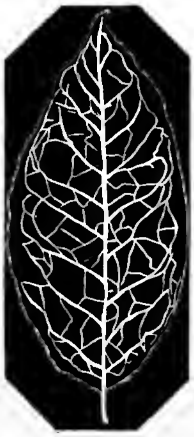

FIG. 4.

No. 5. American leaf strips (Kentucky). Size, 24in. by 10in. This leaf closely resembled No. 1 in appearance and structure, and No. 4 in size. Deeper in colour than any English sample, and reddish-brown. Moderately strong aromatic odour.

No. 6. American Western strips. Size, 18in. by 8in. This leaf was almost exactly the same in appearance and structure as No. 3. Deeper in colour, but not reddish brown. Dark dull-brown, similar to No. 3, but deeper. Slight aromatic odour.

No. 7. German. Size, 15in. by 6in. Very dark in colour, almost black. Thin leaves, not very strong. Veins tough and stringy. Strong odour, but not aromatic.

The samples 5, 6, and 7 were selected—Nos. 5 and 6 on account of similarity to English leaves, and No. 7 as being of European growth. They were also dried at 100° C.

The dried leaves of the seven samples were then remeasured, and the weights notified, and from these data a rough idea of the relative weights of the seven samples was obtained, by calculating the weight in grammes of one square foot. These results are only approximately accurate, owing to the difficulty of measuring the area of such irregular shapes as those of tobacco leaves. They are, however, useful and of interest. The following are the results :—

WEIGHT IN GRAMMES OF ONE SQUARE FOOT OF LEAVES DRIED AT 100° C.

No. 1	2	3	4	5	6	7
13·4	7·5	11·5	8·8	7·5	8·6	8·8

It will be seen that in the English samples Nos. 1 and 3 the weights per square foot are nearly double those of Nos. 5 and 6, to which they respectively correspond in appearance, etc. During the process of fermentation leaves undoubtedly lose weight, and very considerably so, but whether they would lose so much as the difference above is very doubtful. The samples were then broken up, the mid-ribs removed, and the remainder crushed up into a coarse powder, and thoroughly mixed, to obtain a proper homogeneous sample. It was this perfectly dried sample at 100° C. that was taken in all cases for analysis and experiment, and all results expressed in percentages of leaf, refer to the leaf as being in this condition, the only one which could be relied upon for constancy.

The amount of ash was first determined, with the usual precautions, and gave the following results :—

PERCENTAGE OF ASH.

No. 1	2	3	4	5	6	7
25·28	22·87	21·19	23·63	16·19	21·41	19·63

In every case the ash was white. In burning the English samples it was found necessary to continue the heating from the first, or they would not burn, and the carbon at a dull-red heat burnt off very slowly. In fact, it was with difficulty that the last traces were oxidised. No self-supporting combustion took place at all. On first heating, an oil distilled off, which burnt with a very luminous flame, especially so in No. 3, which also burnt altogether more readily than the others. The foreign leaves, on the other hand, burnt off very readily, and when once ignited continued to burn for some time without continuation of the heat. The exact causes of this difference in burning properties will not be discussed here.

From the above results it will be seen that the ash in the English tobacco is very high. This is of importance, as showing that the soil has been highly manured, and that the plant has been probably forced. This is rather unfavourable, and assuming that the leaves lose weight in fermentation, the percentages of ash in the fermented leaves would be still higher. Taking twenty per cent. as the probable loss in weight during fermentation, the resulting figures would then be in

No. 1	2	3	4
31·6%	28·6%	26·5%	29·5%

—unusually high results. The highest ash recorded in connection with tobacco leaves is not over 23·0 per cent., and the average is very much below this.

PERCENTAGE COMPOSITION OF ASH.

	No. 1.	No. 2.	No. 3.	No. 4.
Potash (K_2O)	8·02	10·15	7·38	9·09
Soda (Na_2O)	4·42	4·84	4·15	4·64
Lime (CaO)	41·02	38·66	43·16	41·26
Magnesia (MgO)	3·96	3·61	3·92	3·36
Chlorine	28·02	26·95	28·52	27·01
Carbonic Acid (CO_2) (by diff.)	11·85	12·60	9·69	10·95
Sulphuric Acid (SO_3)	1·95	3·72	1·55	3·80
Phosphoric Acid (P_2O_5)	2·61	2·78	2·86	3·31
Silica (SiO_2)	1·13	2·76	1·89	2·72
FeAt	nil	nil	nil	nil
	106·31	106·07	106·12	106·11
Deduct ox. eq. for Cl	6·31	6·07	6·12	6·11
	100·00	100·00	100·00	100·00

A complete analysis of the ash was then made of the English samples, which gave the results shown in table at foot of preceding page.

The usual methods of analysis were employed, and therefore need not be detailed.

The ashes of the foreign samples were not analysed. There are many already recorded.

The figures obtained above are very important and useful, and in one or two cases rather remarkable. The most important constituents are the alkalis and the lime. The low percentage of potash, and the high percentage of lime, speak very badly for the quality of the ash, which should contain a much larger proportion of potassium to lime. The high percentage of chlorine is a most remarkable result, and one also detrimental to good quality. The low percentage of carbonic acid is no doubt due, to a certain extent, to the excess of lime over potash, a certain amount of caustic lime being produced at the dull-red heat required to burn off the carbon. Sulphuric acid is fortunately low, and the phosphoric acid is much below the average. Taken altogether, the ashes in the four samples, although varying in percentage in the leaf, seem to be practically the same. Nos. 1 and 3 seem to go side by side in what little difference there is, and the other two are also very close to each other. It will be remembered that Nos. 1 and 3, as also 2 and 4, showed a similarity in weight per square foot.

The total nitrogen was then estimated. The method employed was the combustion method with copper oxide in vacuo. To ensure complete combustion of the organic matter present the substance was mixed with an excessive amount of copper oxide in a fine state of powder, and ground down in the mortar with it, then placed in the combustion tube with the copper roll and burnt in the usual manner. The following are the results :—

PERCENTAGE OF TOTAL NITROGEN.

No. 1	2	3	4	5	6	7
4·62	4·16	4·67	4·65	4·33	3·52	4·24

The total amount of nitrogen is of no particular assistance in deciding as to the quality of a tobacco, but is still of interest, as showing the amount taken up by the plant from the soil. What is present in the case of the English samples appears to be all organic nitrogen, as the leaves were tested most carefully for nitrates, and not a trace could be found. This observation applies to the fleshy part of the leaves only, as the veins contained small traces of nitrates and the mid-rib considerable traces. Nitrates were found in the fleshy part of the American samples, however, although in very small quantities.

The condition in which the nitrogen existed was not thoroughly investigated ; but sufficient was done to cast very serious doubt on the existing ideas of the changes by fermentation and the causes of the combustibility of tobacco.

This subject is being pursued, and I hope at some future date to refer again to it.

The amount of soluble matter in the leaf was next determined. This was done by heating a weighed quantity with distilled water for one hour to a temperature of 80° C. on a steam-bath, filtering off the solution, washing the residue, drying it at 100° C., and weighing it. The following figures were obtained :—

	No. 1	2	3	4	5	6	7
Soluble extract %	58·00	58·64	56·55	57·11	45·76	39·70	38·27
Residue	42·00	41·36	43·45	42·89	54·61	60·30	61·73

The results agree very well in the case of the first four samples, but the percentages of soluble extract are very high. It is recorded, in connection with foreign tobaccos, that the highest extractive obtained in this way was not over 55·0 per cent., and the average is about 10 per cent. lower, so that the extractive in the above four samples is excessive, and tends to confirm the previously-expressed opinion that the plants have been forced.

The amount of ash contained in the dried leaves after extraction with water was next ascertained, as also the amount of nitrogen, with the following results :—

PERCENTAGE OF ASH AND NITROGEN IN THE RESIDUE FROM AQUEOUS EXTRACT.

	No. 1	2	3	4	5	6	7
Ash	10·89	11·40	11·71	11·61	13·22	18·78	11·11
Nitrogen	4·13	3·06	4·25	3·29	3·45	3·21	4·45

It is here worthy of note that the dried residual, or washed leaves, burnt free from carbon much more readily than the original leaf. The above results were calculated into the percentages on original leaf by allowing for soluble extract, and the amount of ash, as also nitrogen, extracted by water was obtained by difference.

PERCENTAGE OF ASH EXTRACTED BY, AND INSOLUBLE IN, WATER.

Ash	No. 1	2	3	4	5	6	7
Extracted (by diff.)	20·71	18·16	16·11	18·65	9·27	10·09	10·72
Not extracted	4·57	4·71	5·08	4·98	7·22	11·32	8·91
	25·28	22·87	21·19	23·63	16·49	21·41	19·63

These results are very important ones, and leave very little doubt as to the artificial nature of the plant. The leaves are immature. The amount of mineral constituents not extracted by water, and which are consequently those forming part of the leaf itself, is exceedingly low in all the English samples, while the amount extracted by water is very high ; thus showing the superficial nature of the mineral constituents.

The high figures above in the four English samples, showing the soluble mineral constituents, no doubt account, to a large extent, for the high percentage of soluble extract of the original leaf.

The amount of soluble and insoluble nitrogen is given in the following table :—

PERCENTAGE OF NITROGEN EXTRACTED BY, AND INSOLUBLE IN, WATER.

Nitrogen	No. 1	2	3	4	5	6	7
Extracted (by diff.)	2·89	2·90	2·82	3·24	2·45	1·59	1·50
Not extracted	1·73	1·26	1·85	1·41	1·88	1·93	2·74
	4·62	4·16	4·67	4·65	4·33	3·52	4·24

It will be seen that a similar result, in a less marked degree, is obtained here, as in the case of the mineral constituents—a higher ratio of soluble nitrogen to insoluble in the case of the English samples than in the case of the foreign. The insoluble nitrogen may be taken to roughly represent the albumenoid nitrogen, as the determination of the albumenoid nitrogen in three of the above samples proved it to be so.

An experiment was next conducted with a view to ascertain the amount of internal combustion that took place when the leaves were heated without contact with air. Unfortunately, these experiments did not prove so simple as was anticipated. Weighed quantities of each sample were placed in small combustion tubes, closed at one end and drawn out at the other, and connected with a Sprengel pump. When a vacuum was obtained the tubes were heated to very dull redness, about the same temperature being employed in each case. The gases which were produced were collected and measured. These gases were found to be mixtures of $CO.CO_2.N$ and hydrocarbons. They were not completely analysed, but the object of the experiment was kept in view, and the oxides of carbon were determined. The CO_2 was absorbed by potash, and the CO by cuprous chloride. In this way was obtained the amount of carbon oxidised within the leaf itself. The following are the results:—

CUBIC CENTIMETRES OF GASES COLLECTED FROM ONE GRAMME OF LEAF BURNT IN VACUO.

No. 2	3	4	5	6	7
99·9	91·8	101·7	119·0	137·9	136·1

PERCENTAGE OF CARBON OXIDISED BY HEATING IN VACUO.

Carbon	No. 2	3	4	5	6	7
Oxidised into CO_2	3·38	3·30	3·63	4·46	4·70	4·33
,, ,, CO	0·56	0·19	0·59	0·80	0·89	0·82
Total	3·94	3·79	4·22	5·26	5·59	5·15

The results of these experiments point in the direction anticipated—viz., that the amount of carbon oxidised in the leaf itself is greater in the foreign and fermented tobacco than in the English and unfermented. A larger quantity of total gas is given off, and the amount of both CO_2 and CO is greater. This may be due to the difference of constitution of the leaves, especially between fermented and unfermented, but it may also arise, and probably does so, from the presence of nitrates to a small extent, and more so to the presence of substances introduced at the time of curing. However, too much importance must not be attached to these figures at present. The experiment requires further investigation and probable modification, before results of definite value can be obtained. By some such experiment it might be possible to measure the internal combustibility of tobacco, and this would be an important test. The above experiment tends to show that this can be done, and it is mentioned here as a preliminary experiment of some interest.

Taking the whole of the results into consideration, the opinion may be expressed that they are not, by any means, all unfavourable. It would be out of place at the present time to discuss the possibility of tobacco-growing in this country being a financial success, and it would be presumptive on the above few results to attempt to prognosticate. The object of these analyses and experiments has been to show the comparative qualities of English and foreign tobaccos. This object has been attained, as far as the present samples are concerned, with the result that some of the most serious faults have been laid bare. If the causes of these faults are prevented and guarded against, there is no telling what the result may be. The English leaves are very heavily handicapped, on account of not having undergone the process of fermentation and curing, and consequently, at present, cannot be fairly judged as a tobacco. What the action of fermentation, storing, etc., will be upon them, it is not easy to say. One thing is pretty certain; that is, that the leaves would improve, and they might produce a good tobacco, at any rate better than some of the inferior qualities imported. It must not be forgotten that in the above experiments they have been compared with good foreign samples.

The leaves are favourable as to size and general appearance, but they lack body. They fail in being immature, but the reason for this is known, and it might be remedied. As regards burning, they will not stand the test applied for cigar tobacco. The ash also, as shown above, is not of the most desired composition, and this is a matter of very considerable importance.

The one great point, however, is the fermentation. The exact changes which take place during this process are at present little known. One or two things are evident—that loss of weight takes place, due to oxidation of carbon and probable elimination of nitrogen, and that the mineral constituents remain unaltered, but increase in percentage as the fermentation goes on. These facts would produce in the case of the English samples an abnormal quantity of ash, and it is obvious that an organic substance, being to a degree loaded with mineral constituents which do not lend any aid to the combustion, but on the other hand tend to retard it, will not burn so freely as a similar substance containing less of those constituents. This is evidenced to a certain extent in the interesting fact notified above, that the leaves which had been digested with hot water, and from which four-fifths of the mineral constituents had been removed, burnt much more readily than the original leaf. Comparing these leaves with one another, No. 3, or the long narrow leaf, is decidedly the best, and seems to have thrived better under the circumstances than the others. It is the heaviest in weight and lightest in ash, and moreover burns better than the others. No. 1 is also a heavy leaf, but it is not of such a good quality.

It must not be forgotten that these remarks apply only to the present samples, which were all grown by Lord Harris, and must not be taken as including all English-grown tobacco. I am at present engaged in carrying out similar experiments for Mr. C. De L. Faunce De Laune, on some tobacco grown at Sittingbourne, and I hope to have the pleasure of laying before this Society still more satisfactory results.

My thanks are due to Dr. Hodgkinson for enabling me to conduct the necessary experiments, and also to Mr. D. A. Louis.

Erratum.—In the Discussion on Mr. Trachsel's paper, page 633, December number, 1886, 4th and 5th lines from the end of Mr. C. T. Kingzett's remarks, *for* "90 per cent. of sodium hyposulphite, and only about 10 per cent. of sodium carbonate," *read* "10 per cent. of sodium hyposulphite, and only about 90 per cent. of sodium carbonate."

Liverpool Section.

Chairman: Prof. J. Campbell Brown.

Vice-Chairman: Dr. F. Hurter.

Committee:

J. Affleck.
E. G. Ballard.
Ernest Bibby.
H. Brunner.
J. C. Gamble.
D. Herman.
J. W. Kynaston.

Local Sec. and Treasurer: W. P. Thompson, 6, Lord Street, Liverpool.

Meetings will be held at University College Laboratory, Brownlow Street, on March 2, April 6 (Annual Meeting), and May 4, and the following papers have been promised:—

Mr. V. C. Driffield, "On Boiler Management."
Mr. C. Longuet Higgins, "On the Manufacture of Potassium Chlorate by means of Magnesia."
Mr. J. W. Macdonald, "On the Manufacture of Arrowroot in St. Vincent, West Indies; its Uses and Adulterants."

Notices of Papers and Communications for the Meetings to be sent to the Local Secretary.

A Meeting was held in the Chemical Theatre of the University College, Brownlow Street, on Wednesday evening, February 2, 1887.

PROFESSOR CAMPBELL BROWN PRESIDING.

After the minutes had been read and passed, the Chairman announced that he had placed on the table various samples of salol, and the materials from which it is made, which he thought would prove interesting to the members; also a Zeiss's mineralogical microscope containing several improvements, and a collection of starches from various plants yielding starch.

The Secretary read Dr. Archbold's paper, "On the Manufacture of Starch."

◆

THE MANUFACTURE OF CORN STARCH IN AMERICA.

BY GEO. ARCHBOLD, M.D.

The term "Corn Starch" is exclusively applied to starch made from maize or Indian corn. There is no industry in the United States which has grown so rapidly, and concentrated itself into a small circle of factories, within the last half-century, as this industry. There are now twenty-two factories engaged in the manufacture of starch from Indian corn, and located in six different States, the largest being that at Glen Cove, Long Island, known as the Glen Cove Manufacturing Co. This is probably the largest in the world, there being used each day 336,000lb. of Indian corn in the manufacture of starch.

There are also several glucose factories in different States which also extract starch from Indian corn; but as it is never dried, but immediately converted into glucose or grape sugar, I do not include the latter as starch factories proper.

The number of *wheat starch factories* in the United States does not exceed eight or ten of any magnitude; and careful investigation shows that most of them have no larger capacity than 50 to 100 bushels per diem.

This would indicate a gradual falling into disuse of wheat starch, with a preference to that made from Indian corn.

Cereals containing Starch.—The following is a list of the principal starch-producing cereals, and the percentage yield of starch, according to the published analyses of Krocker (*Ann. Chem.* lviii. 212):—

Wheat Flour	65·21
Rye	61·26
Oats	37·93
Barley	64·63
Buck Wheat	43·80
,, **Meal**	65·05
Indian Corn	65·88
,, **Meal**	77·74
Rice	85·78
Beans	37·71
Peas	38·81

Potatoes yield on an average 18 per cent. of starch. These percentages of starch appear very high; however, they represent high grades of the cereals which seldom or never find their way into the starch factories. During my own experience of over six years in the analysis of Indian corn used in the starch factories, I very seldom found the quantity of starch to exceed 58 per cent. The following analysis of maize represents the average of many samples analysed in the course of one year's working:—

Water	11·20
Starch	51·80
Cellulose	16·40
Gum and Sugar	2·90
Gluten	8·20
Ash	4·80
Fat	4·70
	100·00

I have found from experience that the above represents correctly the quality of corn used in the manufacture of starch.

The following is an average of 114 of the analyses of Indian corn from various parts of the United States, as given on pages 215—217 of the report issued by the Department of Agriculture, Washington, 1883. Assuming 54 per cent. of the 70·69 per cent. of carbohydrates therin stated to be starch, then we have a fair idea of the composition of the Indian corn used in these industries:—

Water	10·01
Ash	1·52
Oil	5·20
Carbohydrates	70·69
Fibre	2·09
Albumenoids (N = 1·67 per cent.)	10·16
	100·00

Process of Manufacture.—The process universally adopted is that known as the alkaline or "sweet process," and which is adapted to the extraction of starch from maize better than any other process known, with one exception, and that is the "sulphurous acid process," which latter has some objections which will be explained later on. However, this much may be said of the SO_2 process in its favour—that it not only gives a larger yield and starch of a very high grade, but much more of the waste material—gluten, etc.—is recovered in a marketable condition; and now that the manufacture of SO_2 has become a staple branch of industry, especially in Great Britain, there is no reason why certain mechanical difficulties, or rather objections, should not be overcome, and this process become as general as the "alkaline."

The reason why the alkaline process is called the "sweet process" is to distinguish it from the "sour or acid process" adopted for the extraction of starch from wheat. This latter consisted in macerating wheat or wheat flour (thoroughly incorporated with water) until the alcoholic fermentation, produced at the expense of the sugar of the wheat and part of the starch converted into fermentable sugar, had thoroughly oxidised or converted the said sugar into acetic acid, which generally requires from three to four weeks. The gluten of the wheat was then readily dissolved, and the starch liberated and separated by mechanical means, and further purified by washing in water. (For full particulars of this old "sour process," and which is still universally adopted in America with very little modification by wheat starch makers, see Muspratt, article "Starch," vol. ii. p. 950; "Ure's Dictionary," vol. iii. p. 745.)

In the treatment of maize this process is impracticable, inasmuch as the gluten of this grain is not so easily soluble in acetic acid solution as in the case of wheat and cereals of a like description, and the time required in its maceration, to obtain a similar result in dissolving the gluten, would not only impair the quality of the starch, but much loss in quantity would be the result.

In extracting starch from maize by the "sweet process," six operations are necessary, of which the following brief synopsis will give you some idea, before I enter upon further details:—

1. The maize is subjected to a cleansing process by means of powerful fans or blowers called "winnowing." This cleans the grain from superfluous bran, dirt, cob, etc. In this process there is generally a loss of over 1¼ per cent. of the grain, from the above bran, dirt, and pieces of cob, etc., being removed.

2. The clean grain is now placed in tanks called "steeps," and covered with water at a temperature ranging from 70° to 140° F., according to the experience of the manufacturer. These steeps vary in capacity, holding from 1000 to 6000 bushels each. This process requires from three to ten days, or until the grain is sufficiently soft to grind.

3. The grinding process, which is generally accomplished by means of burr-stone mills and iron rollers.

4. The straining process, in which the ground corn

is washed and strained through a series of revolving sieves with a current of water. In some factories horizontal square shaking sieves are used.

5. The regrinding of the magma and collection of the impure starchy matter.

6. The treatment with caustic alkali, and separation in the vats called separators.

As it is of the utmost importance to the after treatment of the impure starch with the solution of caustic alkali in the vats named "separators," that as much of the oil and mineral constituents of the corn be removed as is possible, and the nitrogenous matter surrounding the starch of the grain, such as gluten and albumen, be thoroughly softened, so as to be brought to a condition to be acted upon by the alkali, the process of steeping the grain is one of great importance, and various methods have been adopted. In most factories the corn is allowed simply to remain in contact with the water for a period of eight or ten days, or until the putrefactive fermentation has set in, and the corn soft enough to grind. During this period much sulphuretted hydrogen is given off, thereby creating a most offensive odour in the neighbourhood of the works, and even permeating the entire city when winds are favourable. Another process of softening the grain is that known as the Mack process, which is used in Germany in treating rice and maize for starch, and which consists mainly in treating these cereals, in a properly constructed iron tank, with water (with or without alkali), and gas or air pressure. The inventor claims that, by the aid of compressed air, the cereals soften quicker, and yield from 6 to 8 per cent. more of the finished products, thus saving time, plant, and chemicals. When water without the addition of alkali is used with the grain, a tank so constructed, lined with lead or non-corroding material, might be used with advantage. For full particulars of this process see *Dingl. Polyt 256*, 35.

A similar process has been patented in this country since the publication of Herr Mack's process, but it is doubtful if the process will come into general use. It remains to be proved what influence such treatment of the grain would have on the physical condition and appearance of the finished products. The most rational system of this treatment of maize is that used in the Glen Cove Starch Works, previously referred to, and is the system known as the Durgen system. In this factory there are three steeps or tanks, each holding 5500 bushels of corn, which, at 56lb. per bushel, represent 310,800lb. of corn in each tank. Through each of these tanks there is a continuous stream of water heated to a temperature of 130—140° Fahr., which flows for three days at the rate of about 10,000 gallons into each tank per day, after which the corn is sufficiently softened for the grinding process. It has been estimated that no less than 315lb. of solid matter per day is extracted from all these tanks of grain, and which may be divided into—

128lb.	Oil and other organic substances.
61lb.	Albumenoids.
126lb.	Ash of corn and constituents of the water.
315lb.	

In this wet and softened condition the grain is conveyed to the grinding-room, where it is first ground in burr-stone mills, and from thence passed through heavy iron roller mills, when it is carried by wooden spouts and hoppers to the straining department, generally situated on the floor underneath the mills. These strainers consist, first, of large revolving sieves on a slight incline. The first series are of brass wire, and sixty meshes per square inch; the second are of fine bolting silk cloth, such as we find in flour mills. The ground pulpy mass falls with a stream of water into the first series, and then through the second into collecting tanks underneath. The mixed fine and coarse magma which falls from the end of these sieves is then conveyed to the mills, reground, and again passed through these sieves with a stream of water as before, until the water ceases to come through milky. The magma thus exhausted of its starch is then conveyed to a separate room, and, in some factories, dried, and sold as cattle food, or, in its moist condition, as "swill," for hog food. The magma (mixed), as taken from the sieves, has the following average composition:—

Water	62·27
Ash	·27
Oil	1·31
Carbohydrates	28·90
Fibres	1·58
Albumenoids	5·67
	100·00

The above milky fluid, washed from the magma and collected in the tanks underneath the sieves, as above stated, is now allowed to rest or subside for some hours, when the supernatant liquid is allowed to run to waste. The residue, washed and agitated with clean water, is again allowed to repose, and the supernatant liquid run to waste. This second washing is necessary, as, in warm weather especially, the suspended impure starch is apt to turn sour, which would interfere with subsequent operations. The deposited impure starchy matter is now pumped up in a semi-liquid condition into large vats, called "separators," which are generally on the top floor of large factories—this impure starch consisting chiefly of starch and gluten, cellulose and fat.

These so-called separators are huge wooden vats, of a cylindrical form, several feet high, and about the same in diameter, provided with a series of plug-holes in the sides, arranged towards the bottom in equal distances (generally six to twelve inches), and the vat is provided with a mechanical stirrer with necessary gearing. In all well-regulated factories there is generally a series of such vats. The impure starchy matter being pumped into these vats, is diluted with clean water and the agitators put in thorough motion; and here is added cautiously, by degrees, a solution of caustic soda of a gravity 7—8° Baumé until the milky liquid has changed to a greenish yellow colour. The agitation is then continued for some hours, so that when a sample taken from the vat or separator in a glass beaker separates into two layers, the bottom layer dark coloured, and the upper pure white, being the starch.

It may be here remarked that the glutenous or nitrogenous matter of corn consists of two kinds—one which is dissolved by a solution of caustic alkali, the other which is precipitated, and is of a dark yellowish-green colour. The separation being complete, the machinery is stopped and the separated starch and glutenous matter is allowed to deposit, and the supernatant solution of gluten, oil, etc., is allowed to run to waste, and the deposited starch and glutenous matter washed and agitated with water, and allowed to stand at rest for fifteen to twenty minutes to allow the insoluble gluten to subside, when the first plug is drawn, and the starch suspended in the water is allowed to flow into a properly arranged gutter to vats underneath; then the next plug, and so on until the last plug has been drawn. The plugs are replaced and the vats again filled with water, and the operation repeated as before. This operation, called the syphoning process, is generally repeated three times, and the three runnings of starch are collected in three separate vats forming the three grades of starch of the factory. The deposited matters, nearly exhausted of starch by the above means, are all collected and run over what is called the inclined table, which is a series of wide gutters, side by side, sixty feet long, with a fall of from three to six inches at the lower end. The deposited matters are allowed to flow evenly and slowly with a stream of water, the light materials running off the end to waste, while the starch deposits in the gutters.

The starch (1, 2, and 3) syphonings, as above stated, being collected in different vats, are allowed to repose, the supernatant liquid being run to waste ; and then the starch is well agitated with water—in some cases, at this stage, it is necessary to resyphon as before.

During these operations in summer, when the atmosphere is hot, it is necessary to keep the starch in this semi-liquid state cool, and large lumps of ice are kept floating in the vats.

These three grades of factory starch, produced as above, being clean, are again agitated with water and allowed to flow through a fine sieve of bolting cloth into oblong tanks of wood, called "settlers"—the cloth retaining any fibre or glutenous impurity while the finer cells of starch run through with the water. The starch now deposits in these tanks hard and firm on the bottom, while the water can be run off clear to the surface of the starch.

The next stage of the manufacture is to collect this deposited starch in moulds : these moulds are oblong boxes with a perforated bottom. A piece of muslin is damped with water, and packed in the bottom and sides of these boxes, so as to form a perfect lining of the damp muslin. The moulds so prepared are all arranged on stands side by side, and the deposited starch dug out of the settlers and firmly packed in these moulds to the brim, and as the moisture drains, and the starch subsides in the moulds, more starch is added until it ceases to further settle ; in this condition it is allowed to remain for some hours, when the moist starch (which now contains some 60 per cent. moisture) is turned out on to a table, and the oblong block cut through into equal and convenient sized blocks or squares. These pieces, or squares, are then placed on an absorbing medium, or floor, which is generally made of porous brick covered with a layer of plaster of Paris cement ; this floor is heated and dried by means of a series of steam pipes underneath. After being exposed on this warm absorbing surface some hours, the starch contains over 45 per cent. moisture, and is ready for the crusting process. That is, the blocks are placed side by side on a rack, shelf, or shelves, in a kiln, and allowed to remain therein, exposed to a heat of 120° to 130°, until they assume a yellowish brown crust on the outside (this crust generally varies from ⅛in. to ¼in., more or less, in thickness), when they are taken out, and the crust removed —when the interior is perfectly white, the heat having removed the impure matter to the outside. In this form it is wrapped in paper, and again returned to the kiln, and exposed to a temperature of 156° F. to 176° F. and allowed to remain therein exposed to such a degree of heat for a term of three to seven days, or even two to three weeks, according to the nature and size of the crystals required (the pieces of starch of commerce are called crystals in factory language). If the higher temperature and short period in contact therewith be used, small pipe crystals are the result. If the lower temperature and longer time, the starch is obtained in larger chunks and more irregular. These various forms of lump starch are in great demand in the American market.

The starch, as it comes from the kiln in this form, and when taken from the paper, falls into these numerous pieces and forms. Sometimes a large, roundish piece in the centre (called a boulder) still retains its moisture as steam, and is of a fine nature, but, on being thrown amongst the hot starch, assumes the same character as the rest.

Starch from the kilns is practically dry, containing from ½ to 1 per cent moisture, but, on exposure to the air, again takes up moisture, and then retains its commercial condition with 15 per cent. water as moisture.

A sample of starch, taken in the evening, practically dry from the kilns—*i.e.*, containing ½% H_2O—was allowed to remain in the office till the following morning in an open box, was found to have absorbed 5 per cent. moisture, which it had gained from the atmosphere. The larger the pieces, the larger the percentage of moisture will be absorbed. And, even exposed in a comparatively dry store-room in barrels for a length of time, the moisture absorbed varies from 10 to 15 per cent., adding to the original weight of starch. This fact is taken advantage of by some manufacturers as a source of revenue.

The most careful manufacturer, with the most perfect machinery and arrangements, never obtains more than 28lb. on an average of starch per bushel of corn of 56lb., being 50 per cent. of the above average analysis of corn.

The loss of starch by this so-called "sweet process" is invariably 4 per cent., and in some instances known to me, the loss exceeds 8 per cent., which proves carelessness or unskilled workmanship.

The above sketch of the alkaline process describes that which is universally used by the starch makers in the United States with very little variation. The scrapings, crustings and sweepings from the floor, together with the starch collected on the inclined tables, or gutters, called "tailings," are in some factories worked with subsequent batches of starch. In other cases, and I venture to say many, this is dried, ground, and placed in the market as corn flour, "starch flour," or farina. Lately, a quantity of the latter was handed to me for analysis, which had been bought as "potato farina," and invoiced as such by a sausage manufacturer in Syracuse, N.Y. Microscopic and chemical analysis revealed its true nature, as an article unfit for human consumption, being full of microscopic animalculæ, etc.

As previously stated, it is of importance in the early stage of the treatment of the corn to remove as much as possible of the oil and mineral constituents of the grain by steeping, in order that the starch may be rendered as pure as possible, and, as an incidental product, to save all the refuse that can with economy be prevented running to waste. However, in my experience as chemist in a large factory, and past experience in similar factories as to which I have been consulted, careful scientific investigation has proved that, as a rule, not more than 13·7lb. of actual dry refuse matter as hog food is recovered in the treatment of corn, per bushel of 56lb., the 56lb. of corn being represented as follows :—

Starch recovered	**28·000lb.**
Dry refuse as food	**13·700**
Bran (in clearing process)	**0·728**
Original H_2O of corn	**5·626**
	48·054
Actual loss	**7·946**
Total	**56·000**

The above figures show an actual loss of practically 8lb. of the solid constituents of the corn, and which may be divided among the various constituents of the corn as follows :—The above 13·7lb. recovered as *actual* dry food is generally recovered as containing 62 to 80% moisture, and sold as such, seldom in a dry state, and taking the analysis given in a previous part of this paper, which is a very correct average of commercial "starch feed," it is shown to contain 62·27% H_2O, therefore the above 13·7lb. would represent 35 pounds per bushel of moist refuse recovered from 1 bushel of corn as hog food.

The wasted matter is, therefore, divided among the constituents, as follows :—

As showing the distribution of the loss among the various constituents of the corn, the following table is calculated to 2775 bushels, at 56 pounds to the bushel, or 155,400 pounds of corn, which is about the average daily consumption of corn in an institution known to the writer—

	Corn per cent.	CORN IN POUNDS.	Food per cent.	Food in Pounds Recovered.	Total Loss in Pounds.
		2775 bushels at 56lb. = 155,400lb., less 2000lb. dirt = 153,400lb.			
Water	10·01	15,401½	62·27	62,510	2,031½
Ash	1·52	2,331½	0·27	300	2,031½
Oil	5·20	7,977	1·31	1,305	6,672
Carbohydrates *	70·69	108,138½	28·90	29,015	1,693½
Fibre	2·09	3,206	1·58	1,610	1,596
Albumenoids	10·46	16,045½	5·67	5,730	10,315½
	100·00	153,400	100·00	100,500	22,308½
* Starch .... =	50	77,700	trace	trace	trace

The above table will give some idea of the loss of solid matters other than starch, in a factory of large dimensions, and which is entirely caused by running away with the various waste waters, a glance at the quantity of albumenoids thus wasted—over 10,000 pounds daily in the above instance, and, so far as my own experience in the connection with such factories, the above gives a fair and average idea of the waste of valuable products.

This quantity of nitrogenous matter one would imagine could easily and profitably be recovered, and utilised as a source of nitrogen, ammonia, etc., in its crude form. Some years ago, the author tried to interest starch manufacturers in this direction, he having been offered the highest market value, by respectable manufacturers of fertilisers and others, but through want of technical knowledge and comprehension on the part of the manufacturers of starch, received no encouragement, they preferring to allow it to run to waste.

In a factory, then, claiming to consume annually 56,000,000lb. of corn, what must be the loss? As explained in the previous part of the paper, it is due to the existing ignorance of the processes involved in the manufacture of starch, on the part of stockholders and others interested in such factories.

Chemical and Optical Properties of Starch.—According to "Watts's Dictionary Chem." v. 408: "Starch is a white shining powder, soft to the touch, grating between the fingers or the teeth, sometimes consisting of amorphous masses, but more frequently of granules recognisable by the microscope." These granules are of various "diameter [from $\frac{1}{30}$ to $\frac{1}{600}$ of a line (Fritzsche); from 0·185 to 0·002 millimeter (Payen)] and various form, have commonly a small eccentric nucleus, surrounded by layers arranged concentrically one over the other. These envelopes increase by the successive deposition of new layers within the old ones, so that each layer is younger and less compactly aggregated than the one which immediately surrounds it, and since the layers are for the most part of variable thickness they cause the granule to deviate gradually in form from the originally spherical nucleus and assume for the most part an ovoid form. According to Maschke, the starch globules appear like bundles of three concentric bladders, with light and dark rings, the light rings being formed of insoluble, the dark of soluble starch, and enclosing the centre cavity of the innermost bladder, which is either empty or filled with amylone."

The starch granules from corn have a diameter of 0·030 millimeters, the specific gravity being 1·5 at the normal temperature. Starch of inferior quality has generally a "golden or yellow tinge" when broken, which indicates the presence of gluten. Some years ago commercial starch from corn was said to be (U.S.A.) of this latter tinge. However, the inroads of science upon ignorance have dispelled this idea. Regarding the chemical composition of starch, there can be no doubt but that the conclusions arrived at by Salamon (*Jour. f. Prakt. Chem.* 1883, page 28) are correct, and that the empirical formula of starch is $C_6H_{10}O_5$, or some multiple of it $xC_6H_{10}O_5$, and which the author has had an opportunity of proving during considerable work on corn starch, which he hopes to communicate to the Society in a subsequent paper, supplementary to the present.

Commercial Starch.—Experience has proved that three grades of starch may be extracted from corn, differing only in their degree of purity, or freedom from the other constituents of the grain, and from these three grades are put up the various brands upon the market under a variety of names, and for a variety of purposes.

Upon the removal from the drying kilns, starch will seek and find an equilibrium of H_2O with the surrounding atmosphere, which may be readily understood as follows :—

	Starch.
Starch dried at 100° C. in vacuo (is completely dry)	=100%.
" " 15·5 " (contains 10% H_2O)	=90
" " 20 in air containing 0·6% H_2O = 18·6% H_2O	=81·2
Starch dried in air saturated with moisture = 35·7% H_2O	=61·3

Experience thus bears out the statement of the late Dr. Muspratt: "When starch, which has been dried in moist air for several days, is exposed to the circulation of a dry atmosphere, it parts with a further quantity of H_2O, which reduces the percentage of this ingredient to 18 per cent. Thus dried it constitutes the average commercial starch." The following analyses of two samples of starch will give some corroboration of this. No. 1 represents a sample of maizena (pure corn starch), as taken from the kiln and placed in the desiccator after being weighed. No. 2 is a sample of same starch taken from a package put up for commercial use, from a store :—

	No. 1.	No. 2.
Starch	98·5	90·6067
Fibre	0	0·0
* Ash	0·3	0·2758
H_2O	1·2	9·1175
	100·0	100·0000

The above represents a very high grade of starch for cooking purposes, and the highest that can be obtained commercially ; and the longer such starch is exposed to the atmosphere the more H_2O it would absorb, which would corroborate Professor Muspratt's statements—namely, that starch exposed to the atmosphere contains 180 in 1000 of H_2O. Certain manufacturers in the U.S.A. have made a claim (based on the analysis of their starch by a food analyst in London) that "their starch contains 99·8 per cent. of chemically pure starch." Such a standard of purity could not exist commercially. Even assuming that the starch was dried in vacuo at 100° C., the amount of ash would be nearly 0·5 per cent. ; and a careful study of the above facts relating to the absorption of H_2O from the air, etc., show that such an analysis would be an utter impossibility, and more especially with a starch after a voyage across the ocean.

On the technology of this important industry I will treat at greater length on "The Composition of the Various Commercial Starches of America," in my subsequent paper.

DISCUSSION.

The CHAIRMAN said they had heard a very interesting paper, but there were one or two points on which he thought they might be enlightened. The "grade of starch" was a commercial phrase, which he thought might with advantage be explained. It might refer to the size of grain, or to the composition, or simply to the colour. There was a mania on the part of commercial people for some particular colour in many articles—for instance, "whiteness." Now "whiteness" did not always indicate the purity of an article. The whiteness of cream would not indicate that it was pure. The "grade" of starch might be measured by its whiteness, and this whiteness might be obtained at the expense of its good qualities. They were told in the paper how the different grades were obtained, but he would like to know what was meant by a *grade* of starch? Another thing which struck him was that in choosing the substance for the manufacture of starch many things were preferable that were really of less actual feeding value than others. They would reject beans and lentils, which were really very much more valuable substances than some of those which held more starch, because, in fact, the value of albuminous matter for feeding purposes was very much greater than starch. Starch was an essential constituent of food, and was a less costly one than the albuminous ingredients. Maize was comparatively rich in albuminous constituents ; it was not so rich as beans and peas, but was much richer than rice or wheat. Therefore, for economical purposes, it was not desirable that the preservation of the starch should be the great sole object of the manufacturer.

Dr. KOHN asked what led Dr. Archbold to doubt that $(C_6H_{10}O_5)n$ was the correct formula for starch? It had, he thought, been perfectly clearly established.

The CHAIRMAN, in proposing a vote of thanks to the writer of the paper, stated that a report of the discussion would be submitted to Dr. Archbold, and his replies would subsequently appear in the Journal.

ON THE DETERMINATION OF SULPHUR IN PYRITES.

BY JAMES W. WESTMORELAND, F.I.C.,

Associate of the Royal School of Mines, London.

ALTHOUGH much has been written within the last few years regarding the estimation of sulphur in pyrites, yet at the present time the comparison of the results obtained by various operators is far from satisfactory, and this will not occasion surprise when the details of the methods used in various assay offices and laboratories are examined.

The following process was in use some time ago in a copper assay office, where sulphur tests are made :—The ore was powdered in a wedgwood mortar, dissolved in nitric acid, with the addition of a little hydrochloric acid, diluted with rain water and filtered, excess of solution of barium chloride added to the filtrate, the precipitated barium sulphate collected on English blotting paper, washed with rain water, ignited and weighed. The acids and rain water contained a notable amount of sulphur, while the blotting paper allowed some barium sulphate to pass through its pores ; and when it is stated that the operators did not know that silica (sand) was insoluble in hydrochloric acid, the extremely valuable nature of the results will be apparent. Tests made in this way were used to check the vendors' assays (made in a somewhat similar manner) on 1600 to 2000 tons of pyrites per month ; and the settlements were at least one per cent. above the truth. Sulphur at this time being 6d. per unit, the loss to the buyers varied from £40 to £50 per month.

The following assays of samples of pyrites, in which my results are compared with those of another operator, will show the extremely variable character of these tests :—

SULPHUR ASSAYS IN PYRITES.

J. W. W.	Vendors' Assays.	Settled Produce.

* Ash chiefly phosphates of the grain.

The following are assays of one month's deliveries of pyrites :—

Vendors' Assays.		Settled Produce.	J. W. W.
49·7	49·2 or refer.	49·0	48·83 48·79
49·9	49·5 or refer.	49·2	49·18 49·15
49·8	—	49·3	49·12
49·7	49·5 or refer.	49·2	49·10
49·5	—	49·1	49·06
49·4	—	49·0	49·37
49·8	49·2 or refer.	49·1	49·00 49·06
49·8	—	49·4	49·28

While my results on the above series of samples are, as a rule, much below those of the vendors' assayers, in another series with another analyst my principals received a letter from buyers stating that my results were considerably higher than those made on behalf of the vendors, who would probably be complaining to their analyst of the low results he returned. On investigation it transpired that the vendors' assays were returned on the ore as received, while my assays were reported on the dry ore without this fact being stated on the certificate. More recent assays, however, have shown that his results were still seriously below mine, and it became the practice to return a produce 0·50 per cent. below my results on these samples :—

Vendors' Analyst.	J. W. W.
48·8	49·70..49·61
48·7	49·11

The principal methods which have been suggested for the estimation of sulphur in pyrites, are noticed in Dr. Lunge's "Treatise on the Manufacture of Sulphuric Acid." Although Teschemacher and Smith pointed out the necessity for the removal of all nitric acid, before precipitation with barium chloride (*Chem. News*, vol. xxiv. p. 61—64), and the inaccuracy is also referred to by Deutecom (*Chem. News*, vol. xlii. p. 317; *Zeits. Anal. Chem. 1880*, 313), I believe precipitations in nitric acid solutions are made by some assayers at the present time.

Recently, the paper by Dr. Clark, taking exception to the results obtained by a modification of Dr. Lunge's "old process" (*Jour. Soc. Chem. Ind.* 1885, p. 329), and in which he proposes to decompose pyrites by heating in a muffle with magnesia and sodium hydrate, has revived the controversy regarding the accuracy of various methods; and communications from Drs. Clark and Lunge appear in this Journal, 1885, pp. 449, 573, 724. Dr. Lunge objects to any fusion process on the ground that any sulphur present as galena or heavy spar would be estimated, but is silent on the subject of sulphur combined with zinc, which he states ("Sulphuric Acid and Alkali," i. p. 108) is of no use to the alkali manufacturer. I agree with Dr. Clark, that with the cupreous pyrites used in England the whole of the sulphur combined with lead and lime is estimated by either of Dr. Lunge's methods, and some experiments I have made confirm the opinion that the low results obtained in some laboratories were due to the large amount of hydrochloric acid used in washing the sulphate of barium precipitate.

Mr. Pattinson has shown (*Jour. Soc. Chem. Ind.* 1885, p. 724) that the results of Clark's method and Lunge's "new method" are concordant. I hope to show that the results obtained by Lunge's "old process" ("Sulphuric Acid and Alkali" i. p. 102) agree closely with those given by the new process ("Alkali Makers' Pocket Book," p. 82), which is, therefore, a needless elaboration. The new method is also liable to losses caused by an extra filtration and washing, and by sulphur retained in the peroxide of iron precipitate, while sulphur is liable to be introduced by the ammonia and hydrochloric acid used for acidifying. In the majority of the papers dealing with the estimation of sulphur there are no experiments given in which substances of known composition are operated on, concordant results only being quoted, which may or may not have been affected by a constant error which has escaped detection.

Being aware that in many cases where an amount of crystallised barium chloride slightly in excess of that required by theory had been used as the precipitant in solutions of pyrites, the filtrates from the $BaSO_4$ precipitate were in a state of unstable equilibrium, and would give precipitates either on the addition of dilute sulphuric acid or solution of barium chloride, I made a series of experiments with protosulphate of iron, double sulphate of iron and ammonia, ammonia iron alum, and pure recrystallised sulphate of ammonia, using 55 grains of crystallised barium chloride to 5 grains of sulphur approximately present (5 grains sulphur requires 38·1 grains $BaCl_2$, 2aq.). The results of the precipitations from ferrous solutions confirm Teschemacher and Smith's statement that the percentages so obtained are above the truth, while the other tests give results as a rule slightly under the theoretical percentage. The experiments were made by dissolving the salts, diluting to 20oz. bulk of water, boiling, adding gradually the hot solution of barium chloride, and allowing the solutions to stand overnight. In all cases the acids and water used were tested to make sure no sulphur was present in them.

SULPHUR EXPERIMENTS: 55 GRAINS CRYSTALLISED $BaCl_2$,2aq. USED TO 5 GRAINS SULPHUR APPROXIMATELY PRESENT.

Protosulphate of Iron—$FeSO_4$,7aq.—		
Theoretical percentage of sulphur	11·51	—
By direct precipitation as ferrous salt	11·629	11·633
By precipitation after oxidation, evaporation to expel nitric acid, etc., as in pyrites assays	11·473	11·491
By precipitation after oxidation with permanganate of potassium	11·518	11·538
Double Sulphate of Iron and Ammonia-$FeSO_4$,$(NH_4)_2SO_4$,6aq-		
Theoretical percentage of sulphur	16·326	—
By direct precipitation as ferrous salt	16·352	16·337
By precipitation after oxidation, evaporation to expel nitric acid, etc., as in pyrites assays	16·242 16·248	16·193 16·190
By precipitation after oxidation with permanganate of potassium	16·313	16·372
Ammonia-iron Alum—$(NH_4)_2SO_4$.$Fe_2(SO_4)_3$,24aq.—		
Theoretical percentage of sulphur	13·278	—
By direct precipitation	13·197	13·203
Sulphate of Ammonia—$(NH_4)_2SO_4$.--		
Theoretical percentage of sulphur	24·24	—
By direct precipitation	24·201 24·282	24·312 24·201
Average	24·249	

More recently I have made experiments by dissolving recrystallised sulphur, recently fused and powdered, in pure redistilled nitric acid, adding the relative proportions of iron, copper, lead, and zinc, and treating the solutions so obtained as pyrites assays :—

BY PRECIPITATION FROM FERRIC SOLUTIONS: LUNGE'S "OLD PROCESS."

	Grains.	Grains.
Sulphur taken	4·985	4·988
Iron	4·24	4·61
Lead	0·10	—
Copper	0·32	0·30
Zinc	—	0·10
Sulphate of barium	36·28	36·25
equal to sulphur	4·982	4·978

BY PRECIPITATION AFTER SEPARATION OF THE FERRIC OXIDE BY AMMONIA, ETC.: LUNGE'S "NEW PROCESS."

	Grains.	Grains.	Grains.	Grains.
Sulphur	4·997	5·000	5·012	5·019
Iron	4·38	4·38	4·23	4·60
Lead	—	0·10	0·10	—
Copper	—	—	0·32	0·26
Zinc	—	—	—	0·10
Sulphate of barium	36·335	36·225	36·32	36·55
equal to sulphur	4·990	4·975	4·988	5·010

To test the effect of excess of barium chloride on the weight of the precipitate obtained, I made the following experiments on samples of pyrites:—

By precipitation with 55grs. crys. $BaCl_2$.	48·21
„ 65 „	48·24″ S.

			Mean.
By precipitation with 55grs. crys. $BaCl_2$.	46·46	46·36	46·41
„ 75 „	46·44	46·55	46·49
„ 95 „	46·50	46·59	46·51

In the above experiments the precipitates were allowed to stand overnight; the same sample was also tested by precipitation with 55 grains crystallised chloride of barium, and filtration after standing thirty minutes; two experiments gave

46·29 and 46·44; mean 46·36 per cent. sulphur.

I have referred previously to the solubility of sulphate of barium in hydrochloric acid; the following experiments show the necessity for extreme care in the use of HCl when washing this precipitate. Thus, while filtrates from precipitations of pyrites solutions (10 grains pyrites, 55 grains crystallised barium chloride) remained quite clear, or gave only traces of a precipitate on the addition of more barium chloride; when much hydrochloric acid was used in washing the precipitate, the washings, although remaining quite clear on standing, gave, on the addition of barium chloride solution, a precipitate the quantity of which varied with the amount of acid used; and this occurred not only with pyrites assays, but with experiments made with sulphate of ammonia. The quantity of precipitate obtained was much greater than could be accounted for by assuming that other sulphates were precipitated with the sulphate of baryta, and were removed from it by the excessive use of hydrochloric acid, while the fact that the *total* amount of barium sulphate obtained in duplicate experiments was the same with limited and excessive use of acid, supports the view that sulphate of baryta was dissolved and reprecipitated by the addition of barium chloride. Two portions of sulphate of ammonia, containing approximately 5 grains of sulphur, were taken, dissolved in water, slightly acidified with HCl, and precipitated with 55 grains crystallised barium chloride. After standing overnight one of the precipitates was washed in the usual manner, dried, ignited, and weighed. After removing the supernatant fluid from the other precipitate it was washed with an ounce of boiling water, which was, after settling, passed through the filter. The precipitate was then treated with 400 measured grains of strong hydrochloric acid, and twenty ounces of boiling water added, the precipitate well stirred up, and after settling the clear fluid decanted; twenty ounces of boiling water were then poured over the precipitate, and after settling passed through the filter, to which the precipitate was then transferred, washed, dried, ignited, and weighed. The washings of this second experiment were then treated with barium chloride, and the precipitate washed, dried, etc., as usual. The sample of sulphate of ammonia contained a little free acid, which will account for the results being slightly above the theoretical percentage:—

	Grains.		Grains.
Ammonium sulphate taken..	20·56	......	20·591
Sulphate of barium washed with water	36·515	washed with acid	35·625
Sulphate of barium from acid washings	—	......	0·93
Total barium sulphate	36·515	......	36·555
Equal to sulphur per cent. ..	21·39	......	21·37

Pyrites Assays.—In the following tests of pyrites Lunge's old and new processes were conducted as he describes, but employing 10 grains of pyrites and 55 grains crystallised barium chloride for each test, also allowing the solutions to stand overnight. The experiments in which the barium sulphate precipitates were treated with hydrochloric acid were conducted as described above.

Lunge's Old Process.	New Process.	After treatment with HCl.	$BaSO_4$ from Washings. Grains.	Total Sulphur per cent.
50·11 50·10	50·08	48·61	1·105	50·12
44·95	44·98 44·88	43·57	1·005	44·95
49·29	49·25	48·01	1·045	49·41
50·11 49·95	50·10	—	—	—
49·18	49·15	—	—	—
49·12	49·32	—	—	—
48·91	48·78	—	—	—
49·73 49·66	49·57	—	—	—
49·59	49·57	—	—	—
49·07 *49·05	49·05	—	—	—

In concluding this portion of my paper I would refer briefly to the following points: I find it is impossible to expel all the nitric acid from pyrites solutions on the first evaporation (Lunge: "Sulphuric Acid," i. p. 102); on treating the residue with HCl considerable effervescence and evolution of nitrous fumes results, necessitating precautions to avoid loss; and the great difficulty of completely removing all the sulphur from the peroxide of iron precipitated by ammonia. This precipitate should always be dissolved and tested for sulphur, although generally the amount is small. Some operators I believe dissolve pyrites in nitrohydrochloric acid, decomposing the excess of nitric acid by repeated additions of hydrochloric acid and boiling, precipitating from this solution with barium chloride. My experience is that it is impossible to expel the nitric acid completely, and that tests made in this manner are liable to serious error.

With regard to the percentage of available sulphur in pyrites, Dr. Lunge objects to the sulphur equivalent to the lead, zinc, and lime present being estimated as available, stating ("Sulphuric Acid and Alkali," vol. i. p. 108) that lead and zinc sulphates are hardly or not at all decomposed at the temperature of a pyrites burner; and on p. 245 of the same volume he states that burnt ores always contain some sulphate of iron. On examining the analysis of burnt ores by Gibb, quoted by him on p. 589, it will be found that the Tinto, Tharsis, and Mason's burnt ores contain more sulphur as sulphuric acid (SO_3) than suffices to combine with all the oxide of copper, lead, zinc, and lime present. An analysis of San Domingo burnt ore, by Phillips, also shows that more sulphur is present than suffices to form sulphates with all the copper, lead, zinc and lime.

Burnt Ores:—

	Tinto.	Tharsis.	Mason's.
SO_3 per cent.	6·10	5·25	5·80
SO_3 required by PbO, CuO, ZnO, PaO	5·19	3·71	3·87

San Domingo Ore. Analysis by Phillips:—

Total sulphur per cent.	3·66
Sulphur required to form sulphates with Cu, Pb, Zn, and CaO	2·59

---

* The addition of tartaric acid to solutions of ferric salts before precipitation with barium chloride has been recommended to prevent oxide of iron precipitating with the barium sulphate; 50 grains of tartaric acid were added in this experiment, but without any influence on the result.

In an analysis of burnt ore from Norwegian pyrites the figures are—

SO_3 per cent.	6·56
SO_3 required by PbO, CaO, CuO	3·69
SO_3 to ZnO	2·87

6·46 per cent. ZnO present requires 6·38 per cent. SO_3; in this case it is evident some of the sulphate of zinc has been decomposed. If the analysis of burnt ores from Spanish pyrites referred to above are examined, it will be found that the sulphur required to form sulphates with the lime and lead present is relatively small, while the zinc requires a much higher percentage. This is also evident in the following analysis of average samples of pyrites recently made by me—

	(*a*)	(*b*)	(*c*)	(*d*)	(*e*)
Lead	1·38	0·85	1·01	0·53	0·07
Zinc	0·177	0·762	1·06	1·85	—
Lime	0·27	0·183	0·21	0·21	1·03
Sulphur required by lead and lime	0·37	0·21	0·29	0·22	0·59
Sulphur required by zinc	0·23	0·32	0·52	0·91	—

a, *b*, c, *d* are Spanish pyrites, *e* is a sample of Italian ore with 15 per cent. of sulphur.

The quantities of sulphates of lead and lime present when operating on ½ gramme or 10 grain assays of pyrites are so small that there can be little doubt that all the sulphur is estimated as sulphate of barium, and in my opinion the better plan would be (in cases where the pyrites is returned after burning to copper extractors) to deduct the percentage of sulphur found in the burnt ores (making a correction for the lesser weight of the latter) within certain agreed limits from the total percentage; the alkali maker would then without doubt pay only for the actual sulphur of service to him. In other cases an allowance might be made, based on the percentage of lead, lime, and zinc in the ore.

With regard to the various discrepancies I have enumerated, it has been suggested that they form a strong argument in favour of the proposed uniform methods of analysis. While admitting that certain methods—for instance, the bichromatic process for iron assays—are the most accurate, yet I think great caution should be used in recommending that a single method be adopted, especially if it is not free from fault. To illustrate this I may refer to Lunge's "Alkali Makers' Pocket Book," pp. 82, 83, 84. The methods detailed for the estimation of copper and zinc in pyrites are not above criticism, while the process given on p. 84 for the estimation of sulphur in burnt ores would certainly indicate that present as sulphates of lead and lime. The introduction of these standard methods will also probably reduce the status of the chemists employed, and lead to work being done by rule of thumb instead of being thoroughly understood, while it is giving valuable information to people who are too idle or incompetent to investigate the accuracy of the various processes themselves, with the result that if any variation occurs in the material operated on, serious errors are likely to occur and escape detection. I would also point out that while the general principles of the methods which should be used in the estimation of sulphur have been known for years, most serious errors have occurred and escaped detection up to the present time, for which no other excuse than gross carelessness can be given.

In conclusion, I will submit that the results of Lunge's old and new methods for the estimation of sulphur in pyrites are concordant, and express the total percentage in Spanish pyrites; that a moderate excess of chloride of barium should be used when precipitating sulphate of baryta, and that great care should be taken in the use of hydrochloric acid when washing this precipitate.

ON THE TREATMENT OF SOAPMAKERS' LEYS FOR RECOVERY OF GLYCERIN.

BY ALFRED H. ALLEN, F.I.C., F.C.S.,

President of the Society of Public Analysts.

The applications of glycerin are constantly extending. Besides being employed in pharmacy and medicine, it is also used extensively in the manufacture of toilet soaps, for filling gas-meters in situations liable to be exposed to great cold, and for various other purposes. But by far the largest application of glycerin at the present time is in the manufacture of nitro-glycerin, which is used for making dynamite and blasting gelatin to the extent of a good many tons daily.

At present the greater part of the glycerin of commerce is obtained by saponifying fats under high pressure with water and a limited proportion of a base. This process yields a high quality of glycerin, but the fatty acids, which are the primary objects of the manufacture, produce inferior soaps to those obtained by directly saponifying fats with caustic soda.

When the latter method of soap-making is employed, it is usual to separate the soap from its aqueous solution by adding common salt, the soap being practically insoluble in brine of a certain strength. Hence there is obtained, as a waste product, a strongly-saline liquid, containing a certain proportion of glycerin, and it is the treatment of this spent ley that forms the subject of the present paper.

Spent soapmakers' leys have a very variable and complex composition. They usually contain water; glycerin; chloride, sulphate, and carbonate of sodium; a small quantity of caustic soda; and very variable amounts of suspended or dissolved soap, and resinous, fatty, albuminous, and colouring matters. In addition to the foregoing, which may be considered the normal constituents of leys, a number of other troublesome impurities exist in the products of certain works. Thus, at Widnes, tallow and other fats are saponified by means of causticised black-ash liquor, instead of by finished caustic soda. The resultant "Lancashire leys," obtained in salting out the soap, are exceedingly impure, and consequently very difficult to deal with. Besides the foregoing constituents, they contain a considerable quantity of hyposulphites (thiosulphates), besides sulphides, sulphocyanides, cyanides, ferrocyanides, etc. The sulphur compounds, in particular, are very objectionable, for if not removed they cause the production of volatile organic sulphur compounds during the distillation which all recovered glycerin has to be subjected to, and the distilled product is unfit for the purposes of the dynamite manufacturer.

The recovery of the glycerin from soap leys in a state sufficiently pure for conversion into nitroglycerin is a problem which has exercised the faculties of a number of inventors. The history of the subject up to the end of 1881 was discussed by Mr. Charles Kingzett in an interesting paper read at an early meeting of the London Section of this Society (this Journ. *1882*, 78). This paper and the records of the Patent Office constitute almost the entire literature of the subject up to the present time.

As stated by Mr. Kingzett, a study of the specifications relating to glycerin-recovery shows that "it is very much easier to obtain a patent than to make a discovery." Reviewing the different processes described by the patentees, Mr. Kingzett classifies them as designed to effect the following objects: "1. To remove or destroy albuminous or soapy matters, together with any residual soap in the spent leys. 2. To facilitate the removal of the salt, either by employing means to diminish the solubility of the chloride of sodium, in cases where that substance is used, or to substitute another which may be more readily and profitably removed. 3. To economise the cost of concentrating the leys to that point at which the glycerin may be at once employed for certain purposes in its then crude condition, or still further purified by distillation."

To effect the first of these objects, it has been proposed to acidulate the leys, and some inventors then add tannin, gelatin, albumin, alum, chromium salts, iron salts, pyroligneous acid, etc. Stearic acid is employed by one inventor (Bang, No. 4593, 1883), while another proposes to convert the concentrated glycerin into a glyceride by heating it with oleic acid. O. C. Hagemann treats the leys with lime to causticise the alkaline carbonate, and then boils with rosin to convert the resultant caustic soda into a rosin soap, which is removed.

To get rid of the common salt, Clolus (No. 681, 1881) has proposed to saturate the previously concentrated liquid with hydrochloric acid gas, subsequently getting rid of the latter by means of lead oxide or a current of air; while F. Versmann concentrates, and treats the liquid with carbonic acid, by which acid carbonates are formed which are comparatively little soluble in glycerin. Both these inventors recommend dialysis as a further means of separating the salts from the glycerin, and the same principle has been employed with some measure of success by H. Fleming. (Ger. Pat. 13,953, 1880.)

Other inventors (Eng. Pat. 1562, 1881) employ sodium sulphate instead of common salt for precipitating the soap; then neutralise the leys with sulphuric acid, and evaporate and separate the sodium sulphate. In another instance (Eng. Pat. 1728, 1882), the ley is acidulated with sulphuric acid, and after concentration the salts are separated from the glycerin by means of alcohol or wood spirit.

Some inventors obtain a product rich in glycerin by using spent leys instead of water for dissolving the alkali requisite for saponifying fats, while another evaporates the ley till salt begins to deposit, and uses the liquid instead of fresh brine for precipitating soap from solution.

The use of immiscible solvents, such as petroleum spirit or amyl alcohol, for separating impurities from glycerin, both before and after distillation, is proposed by some inventors, while fatty acids are preferred by others.

Of course modifications exist in the details of glycerin-recovery, but the method of treating leys now commonly used is substantially as follows:—The liquid is acidulated, heated by open steam, and the precipitated fatty and resinous matters separated. The clear liquor is neutralised with soda-ash, filtered and concentrated in open pans. The evaporation is continued till the boiling-point reaches 270—280° F. The salt which separates continuously during the process of concentration is removed by perforated ladles, and then usually washed with brine, and dried by means of a hydro-extractor. The liquid is further concentrated till the boiling-point is as high as 300° F. The crude glycerin thus obtained varies greatly in quality. The density is sometimes as high as 1·36, and the proportion of mineral matter usually ranges from 7 to 14 per cent. A considerable proportion of it consists of sodium chloride; but if sodium sulphate has been used for precipitating the soap the proportion of sulphates in the crude glycerin will be correspondingly high.

In any case, the crude glycerin requires to be distilled, which is effected in specially-contrived apparatus with the aid of superheated steam. A second and third distillation are sometimes necessary, and in some cases the distilled product obstinately retains impurities which unfit it for conversion into nitro-glycerin. I am informed that in Germany a good distilled product is obtained from crude glycerins which have not hitherto been satisfactorily worked in this country.

As already stated, the impurities in Lancashire leys are exceptionally troublesome to deal with, and the most notable systematic attempt to purify the product is that patented by Mr. O. C. Hagemann (Eng. Pat. 8051, 1885). After treating the leys with lime, and subsequently boiling with rosin in the manner already described, the inventor neutralises the liquid with a mineral acid, and then adds ferric chloride as long as a precipitate is produced. The precipitate consists mainly of fatty matter and Prussian blue, and is said in the patent to have a marketable value. After separating the precipitate, the purified liquid is treated with hydrochloric acid, heated, and air blown through it for some time. This treatment causes the decomposition of hyposulphites, etc.; but to complete their destruction a solution of bleaching powder is next added until free chlorine is found in the liquor, when the precipitated sulphur is removed and the ley neutralised and concentrated. This process is by no means perfect, though yielding a much improved product.

The treatments with lime and rosin have been abandoned, and I believe the blue precipitate has not hitherto been found to have a marketable value; while purification by bleaching powder has formed the subject of a previous patent. But these are negative objections. A graver one is that the process leaves untouched the sulphocyanides which are present in very considerable quantity in Lancashire leys, and which are perhaps the most objectionable impurity.

It was primarily with a view of removing the sulphocyanides that I was led to devise a method of treating leys, which forms the subject of a patent recently obtained by Mr. B. Nickels and myself, and the process appears to have satisfactorily solved one of the most difficult problems connected with the subject.

Although most, if not all, of the heavy metals form ferrocyanides which are insoluble in neutral or faintly acid liquids, the metallic sulphocyanides are mostly soluble. Thus, whereas solutions of iron, zinc, tin, lead, and copper are all available for removing ferrocyanides from leys containing them, copper solutions alone are capable of precipitating the sulphocyanides. Hence, it occurred to me that copper salts might be advantageously employed for the purpose in question, and a further consideration and experience of their behaviour has shown Mr. Nickels and myself that they possess a variety of attributes which render them curiously well adapted for purifying soap leys. Thus, on adding a solution of a copper salt to soap leys previously rendered neutral or faintly acid, the sulphocyanides are wholly precipitated, and with them are also thrown down any sulphides, cyanides, ferrocyanides, or silicates ; together with albuminous, resinous, fatty, colouring, and a variety of other organic matters. The precipitate settles with great facility, and the filtered liquid is obtained nearly colourless.

If a cupric solution be employed, which in practice is always the case, more or less oxidation of the hyposulphites occurs, owing to the fact that the precipitate consists of cuprous sulphocyanide.

The reaction between a soluble sulphocyanide and a cuprous salt is a simple case of double decomposition, the insoluble white cuprous sulphocyanide being instantly precipitated ($Cu_2Cl_2 + 2NaCNS = Cu_2(CNS)_2 + 2NaCl$). When a soluble sulphocyanide is treated with a cupric salt in concentrated solution, the sparingly soluble black cupric sulphocyanide is first precipitated, and this gradually changes more or less completely into the white cuprous salt. Similarly, when a cupric salt and a soluble sulphocyanide are mixed in solution so dilute as to prevent the precipitation of cupric sulphocyanide, a white precipitate of cuprous sulphocyanide is gradually formed. It is evident that the reduction of the copper to the cuprous condition involves the simultaneous oxidation of a portion of the sulphocyanide. The odour of hydrocyanic acid developed and the formation of a sulphate in the liquid indicate qualitatively the nature of the change, and I have proved by quantitative experiments—(*e.g.*, verification of the ratio :—$6CuCNS : H_2SO_4$)—that the following equation represents the main reaction which occurs :—$6CuCl_2 + 7NaCNS + 4H_2O = 6CuCNS + 7KCl + 5HCl + H_2SO_4 + HCN$.

It would appear from these considerations that the presence of a moderate proportion of a hyposulphite is a positive advantage when sulphocyanides are to be removed from leys, and that if not present in sufficient quantity, the cautious addition of a suitable reducing agent should be practised. When a cupric salt is mixed in neutral or slightly acid solution with sodium hyposulphite, and the liquid is boiled, a sulphide of copper is well known to be precipitated. In the cold no precipitation occurs, but the copper is reduced to the cuprous state, showing that the hyposulphite undergoes oxidation in some manner with conversion into one or more of the thionic acids, but I have not yet ascertained the exact reaction. Oxidation to sulphate is unfortunately very partial.

Whether the copper solution should be added to the leys in the exact quantity necessary to remove the precipitable matters, or whether an excess should be employed, is a detail which experience will quickly decide. As a rule a supplementary treatment with bleaching powder or other oxidising agent will have to be resorted to in order to destroy the remainder of the thionic acids, and if excess of copper has been employed it must be subsequently removed from the liquid by sulphuretted hydrogen, an alkaline carbonate, metallic iron, or other suitable means, either at once or after more or less concentration.

The employment of copper for the purification of soap leys, however perfect chemically, would not be available in practice but for the great facility with which the copper can be recovered from the precipitate. This advantage is peculiar to the use of copper. If compounds of iron, zinc, lead, or tin be employed, the metals are practically irrecoverable from the precipitates. But a copper precipitate merely requires to be dried, ignited in the air, and treated with acid, for the original solution to be re-formed. Or, if preferred, the precipitate, whatever its composition, can be sold to the copper-smelter with the assurance that it will command a price strictly proportional to the copper present. Further, the copper solution obtained by treating spent cupreous pyrites in the wet way (as practised by the Tharsis Company) is eminently suitable for precipitating soap leys, and hence the copper can, under favourable circumstances, be recovered from it without the employment of scrap-iron.

If, however, it be desired to treat the copper precipitate to re-form the cupric solution, a certain modification is desirable in practice. This is owing to the presence of ferrocyanides in the leys, which become precipitated as cupric ferrocyanide, and hence the oxide of copper produced by roasting the precipitate contains an admixture of oxide of iron. To avoid this it will be preferable in many cases to subject the ley to a preliminary treatment. That is, it should be acidulated with hydrochloric acid and treated with the salt of some metal forming an insoluble ferrocyanide. A solution of ferric chloride or sulphate is perhaps the most convenient, as the formation of Prussian blue and subsequently of the red ferric sulphocyanide is so readily observed ; but solutions of zinc, tin, or lead are also available. The bulky precipitate of albuminous and fatty matters mixed with ferrocyanides having been separated, the subsequent addition of a cupric solution causes the complete precipitation of the sulphocyanides as a grey or nearly white cuprous sulphocyanide. This may be ignited, as already described, and the resultant cupric oxide redissolved to produce a cupric solution for treating a fresh quantity of leys ; or it may be employed for the production of a soluble sulphocyanide by double decomposition. Sulphocyanides of sodium, barium, magnesium, etc., are readily produced in this way, while the copper is left in the form of cuprous oxide and can be at once dissolved in hydrochloric acid,* and employed for treating more leys.

I have been induced to dwell at some length on the subject of the removal of sulphocyanides, because the process by which we have succeeded in effecting it is possessed of considerable theoretical interest. The practical value of the process cannot yet be said to have been completely demonstrated, but a series of experiments on a manufacturing scale have been for some time in progress at the works of Messrs. N. Mathieson & Co., of Widnes, and the results so far obtained have been so highly encouraging as to leave little doubt of ultimate success. On the table are a series of specimens representing the operation at various stages as actually carried out on a large scale. The salt recovered is of very satisfactory quality, presenting a marked contrast to that ordinarily obtained from Lancashire leys. So far the character of the glycerin produced on distillation has not been definitely ascertained, but it is confidently anticipated that the very perfect removal of the sulphur compounds effected by the process will enable a very superior distilled product to be obtained.

Although copper salts are of exceptional value for

---

* The cuprous chloride formed is insoluble in pure water, but is dissolved by hydrochloric acid, and is also readily soluble in a liquid containing common salt.

the purification of leys containing sulphocyanides, it must not be supposed that other leys are not materially improved by treatment with copper. On the contrary, I have met with concentrated leys produced in a soap works, where finished caustic was used for saponifying, which were so impure as to be absolutely refused by the distiller. A simple treatment with copper sulphate caused the precipitation of an enormous quantity of impurity, and a change of the crude glycerin from a deep brown tarry semi-fluid to a sherry-coloured liquid of the viscosity of pure glycerin. This improvement is not surprising when we consider that copper forms highly insoluble compounds with fatty acids, resinous matters, albuminous substances, and a number of other organic bodies. In all instances where ferrocyanides are absent, the copper may be recovered as pure oxide by simply igniting the precipitate, so that the expense attending the process is very moderate.

Although Mr. Nickels and I believe that we may fairly claim to have effected an improvement in the treatment of soap leys for the recovery of glycerin, the subject is still far from being exhausted. None but those who have worked practically with leys have any idea of the enormous quantity of salt which has to be separated. It does not appear that the substitution by the soap-maker of the sulphate of sodium for the chloride usually employed materially assists the subsequent operations, so that the removal of the salts still remains to be effected. The fact is often overlooked that glycerin has a far greater solvent power than water for many substances, and hence the problem becomes further complicated. By dialysis the proportion of salts can be materially reduced, and H. Fleming states that by this means a first-class quality of crude glycerin can be obtained, which is practically free from salt, and a second grade which is as good as that which has not been subjected to the process. Much of the salt can doubtless be removed by dialysis, but the operation is by no means perfect, and only a portion of the glycerin is claimed to be recovered in a nearly salt-free condition. In fact, Mr. B. Nickels has found that by continuing the operation, using a diaphragm of parchment-paper, all the glycerin can be caused to dialyse, while certain troublesome resinous impurities remain behind. On the other hand, Fleming has patented the use of a guttapercha membrane, which he states is traversed by salt, but is impermeable to glycerin. I am not aware how far this statement has been found to bear the test of experience. In any case, it is evident that much still remains to be accomplished in perfecting the recovery of a high quality of glycerin from soap leys.

DISCUSSION.

The CHAIRMAN: The subject of Mr. Allen's paper is one of very great importance, particularly from a technical or practical point of view. Unfortunately, it is one I am not at all familiar with. There is only one question which presents itself to my mind, and that is—What occasion is there for the removal of the impurities referred to? I do not quite understand what harm is done by the sulphur compounds if they are not removed.

Mr. DAVIS: I think that in suggesting the sale of the copper precipitate to the smelter, Mr. Allen has rather overlooked the direct commercial value possessed by cupreous sulphocyanides. This has now acquired considerable importance as the starting-point of various metallic sulphocyanides now extensively used by dyers. In fact, for several years past, I have purposely manufactured the sulphocyanide of copper from the crude sulphocyanide of ammonium obtainable from gas liquor, and can confirm Mr. Allen's experience as to the necessity of using a reducing agent if the whole of the sulphocyanide was to be precipitated and no hydrocyanic acid formed. I employ ferrous sulphate as the cheapest reducing agent available. Now that chemists are on the look-out for new sources of sulphocyanides, I think Mr. Allen's process, by which sulphocyanide of copper is obtained as a secondary product in the purification of soap leys, is likely to prove of great value. I am surprised that Mr. Allen doubts that hyposulphites are oxidised to sulphates by cupric salts, as I am in the habit of precipitating copper by sodium hyposulphite, which becomes converted into sulphate.

Mr. DREYFUS: I just wish to correct Mr. Davis with respect to his statement that he was the first to make sulphocyanide of copper. I believe the late Mr. James Higgin made sulphocyanide of copper some eighteen years ago on a large scale, and sold it to calico printers. About twelve years ago I manufactured this article myself, and sold it to the calico printers as a substitute for sulphide of copper in aniline-black printing. I understood Mr. Allen to say that in Germany they had succeeded in making good glycerin by distilling the crude product, a thing which has not been successfully done in England. Is it not possible that in Germany they obtained this result by distilling *in vacuo?*

Dr. GROSSMANN: I have listened with great interest to Mr. Allen's paper, but must say that I have been greatly disappointed at one serious omission, and that is, that Mr. Allen has not given us an analysis of the liquors which result from the manufacture of soap, and which are used for glycerin making. In dealing with a commercial process, it is, of course, of the utmost importance to know exactly the composition of the compounds which have to be worked up. Now, Mr. Allen tells us that the quantity of sulphocyanide in the leys is very considerable, without giving us any data. This does not agree with my personal experience, for to my knowledge the quantity of sulphocyanide in black-ash liquors after boiling down is comparatively small—in fact, black-ash liquors, after boiling down to the utmost concentration, would contain about one or one-and-a-half grms. sulphocyanide of sodium per litre; equal to about one-tenth per cent. by weight. These figures refer to a time when black ash was made in the ordinary way, but since then the tendency has been to reduce the cyanide in black ash, and several patents have been taken out to effect this, one by Messrs. Pechiney & Weldon, and another for treating the liquors from black ash by Messrs. Gaskell, Deacon & Co. It is, therefore, now comparatively easy to reduce the cyanide below the figures which I have mentioned, and I may be excused for saying that with a little attention to the black-ash process, the difficulty in treating the soap leys as regards cyanides could be reduced to a minimum. The question whether it might not some day pay alkali makers to increase the quantity of ferrocyanides and sulphocyanides in their liquors for the purpose of manufacturing these products, thus turning what is now a source of annoyance into a source of profit, is a separate question altogether. But, even in that case, we must not forget that where the liquors have been used for soap making they contain organic and other substances which will be thrown down with the sulphocyanide of copper, and contaminate any product consequently made from it. There will also, in my opinion, always be a considerable loss of copper arising from different causes, and, among others, from the fact that the copper smelter does not pay for the actual quantity of copper, but for the quantity which he will obtain on smelting as indicated by the dry assay, and certain impurities in the precipitate may affect this point to a considerable extent.

Mr. **Thomson**: I understood Mr. Allen to say that the Germans had succeeded in producing glycerin free from colour from soap leys, but that up to the present time this had not been accomplished in England. I believe the French were the first to produce pure glycerin from soap leys. Some years ago I visited the works of M. Clolus, in Paris, and he then showed me some glycerin quite free from colour, which had been prepared by him from soap leys.

Mr. **Allen**, in reply to the Chairman, said: The sulphur compounds cause the formation of volatile sulphuretted organic compounds during the subsequent distillation of the glycerin, and render it unfit for conversion into nitro-glycerin. With regard to Mr. Dreyfus's remarks, what I stated was that in Germany they obtained a product of fair quality by distilling a certain crude glycerin which had not hitherto been successfully distilled in England. The crude glycerin in question was not always obtained from Lancashire leys. I did not intend to imply that a colourless or fairly good distilled glycerin could not be manufactured in England, as it is done very largely, by several firms. Some of the best samples of distilled glycerin, so far as colour is concerned, behave in an unsatisfactory manner on nitration. I am delighted that so high an authority as Mr. Davis should think that the precipitate of cuprous sulphocyanide obtained in his process is likely to have a direct value in the manufacture of other sulphocyanides. I fancied that hitherto Messrs. Gossage cared very little what proportion of sulphocyanides had been present in the black-ash liquors, while, I might remind Dr. Grossmann, that was not the same thing as finished caustic soda. I don't know the proportion of sulphocyanides actually present in the specimens of leys before us, as the bottles are just in the condition in which they were sent me by Messrs. N. Mathieson, but you can see that the precipitate of cuprous sulphocyanide is very considerable. I have assayed several specimens of Lancashire leys, and have found them to vary very considerably in the proportion of ferrocyanides and fatty matters present. The samples I have examined contained not less than one gramme per litre of sulphocyanogen (CNS). This does not at first seem a very large amount, but if it existed in leys containing five per cent. of glycerin, it is evident that the crude glycerin obtained on concentration will contain something like two per cent. of sulphocyanogen, and much smaller proportions than this were found highly objectionable on distillation. I cannot agree with Dr. Grossmann as to the result of the assay of a copper precipitate. In the Cornish dry assay the first operation was usually to roast the ore, and if that were done with cuprous sulphocyanide, or any mixture of that with ferrocyanides, albuminous matters, etc., there would be no difficulty in getting out nearly all the copper by dry assay. In cases where ferrocyanides are present it will probably be found desirable, first of all, to treat the leys with acid and an iron salt, by which means a large amount of fatty and albuminous matters may also be removed, while the precipitate subsequently obtained will consist of approximately pure and nearly white cuprous sulphocyanide.* In other cases it will, doubtless, be found simpler to precipitate everything together by the addition of a cupric solution, roast the precipitate, and re-dissolve the resultant oxide of copper in acid. Treatment with the copper solution removes an astonishing quantity of impurities even from leys produced in soap works where only finished caustic soda is used. The copper treatment can be practised at almost any stage of the concentration, but, so far, the operations on a large scale have been conducted on the leys after evaporation to the point at which salt began to deposit. With regard to Mr. Davis's remarks about the oxidation of hyposulphites, I am myself accustomed to precipitate copper in that way, and the re-action which occurs in a boiling solution is generally represented as follows: — $CuCl_2 + Na_2S_2O_3 + H_2O = CuS + Na_2SO_4 + 2HCl$. Has Mr. Davis verified this, and found complete oxidation to sulphate? In the cold, no separation of sulphide of copper occurs, and I fear the change to sulphate, even in the presence of excess of copper, is not complete. I wish it were, as it would obviate the necessity of a supplementary treatment of the leys with bleaching solution, but that after all is a simple matter.

◆

ON THE INFLUENCE OF MASS ON THE COURSE OF CHEMICAL DECOMPOSITION, WITH ESPECIAL REFERENCE TO TECHNICAL PROCESSES.

BY G. H. BAILEY, D.SC., PH.D.

It is not without some diffidence that I bring before you a subject which, strictly speaking, is more scientific in character than technical; but to those engaged on a large scale the subject is a matter of importance, and if I can accentuate in some degree the desirability of a more definite knowledge of this subject, I shall be satisfied; and perhaps in the discussion there are some who may be able to point out examples of this action which have occurred in the course of their experience.

I propose, by way of introducing the subject, to say a few words about the work and views of Berthollet, which, although not accepted in their entirety at the present day, yet form the basis for the dynamical study of the course of chemical reaction.

Berthollet looked upon decomposition as depending chiefly on mass, and considered that such variations as did occur arose from physical causes, such as volatility or insolubility. Take the case of silica. The affinity of silica for bases is only about 1 per cent. of that of nitric acid, and yet silica expels nitric acid from sodium nitrate at higher temperatures, and, where a large excess of silica is used, even at moderate temperatures. This arises from the greater volatility of nitric acid. Again, hydrochloric acid in excess, though a volatile acid, decomposes silicates with the separation of insoluble silica, the direction of the reaction in this case being determined by the factor of insolubility.

It is a well-known fact that silicates are decomposed by alkaline carbonates, and yet some recent results, published by Bunsen, show that carbonic acid at ordinary temperatures will decompose glass, the decomposition in his case having proceeded to the extent of 6 per cent. Similarly, experiments have been tried on the solvent action of aqueous solutions of carbonic acid on the Thomas-slag with a view to utilising the phosphates contained in that slag, and it has been found that it is to a considerable extent dissolved; in fact, Meyer was able to dissolve more than half the lime and phosphoric acid out of such a slag containing 54 per cent. of lime and 22·2 per cent. of phosphoric acid.

One can readily see why silica ought to be avoided in the balling process, and similar caution is required

---

* The precipitate obtained on a large scale was found, after washing and drying, to contain 97 per cent. of cuprous sulphocyanide.

in other processes where higher temperatures are employed. This caution applies with equal force to processes, whether carried out on the large scale or merely as experimental trials, where glass or porcelain are used, and patents could easily be pointed to in which reactions attributed to other causes arise really from the material of which the apparatus is constructed. The second point of Berthollet's views has received more attention in recent times, and it is with this we chiefly concern ourselves.

When two substances are brought together, the reaction which takes place between them is not final and determinate, but its extent is defined by the temperature, by the mass, and by other influences. When, for instance, we bring together barium hydrate and sulphate of soda, we have formed sulphate of barium and caustic soda, but the reaction is always accompanied by a reverse reaction, in which the caustic soda reacts on the barium sulphate, reproducing barium hydrate; so that at any given time we have present, not barium sulphate and caustic soda alone, but all four of the products, and the relative quantities of these depend largely on the masses present.

The New York Oxygen Company produce hydrogen by heating together anthracite and slaked lime. The operation is finished in a very short time, and on passing an excess of steam over the residue in the retorts the reverse action sets in and the slaked lime is reproduced. We can then proceed to submit the materials to the second operation for producing hydrogen, and this may be continued many times without renewing the materials. Whatever other factors come in, there can be no doubt that the excess of steam used in this case controls the direction which the reaction may take. A further instance comes from practical experience in caustic soda making. It has been found that a 2 per cent. solution of carbonate of soda will yield 99·4 per cent. caustic; a 10 per cent. solution, however, gives only 97·2 per cent. caustic; and a 20 per cent. solution gives only 90·7 per cent. caustic. The reaction here is between water, carbonate of soda, lime, and calcium carbonate; and we have a second instance very much resembling the case of the barium hydrate, and where the mass of water defines the course of the reaction.

Interesting examples of the same kind might be obtained from the experiments that have been done in the lixiviation process, the most interesting of which are due to Kolb. He finds that the amount of carbonate obtained increases with a large excess of water, but that the sulphides also increase under these conditions, and this latter more especially when the process of lixiviation occupies considerable time. If such experiments are worthy of being carried out in the complete manner that they have been in this instance, it is worth while to make similar investigations of other processes with a view to determine in precise terms the effect of mass.

Where reactions are made use of in which the chemical affinity is small we have the results of mass action most pronounced; and to take a case right on the borderland of chemistry, where chemical affinity is extremely small, we may consider the case of solution of gases. Dalton and Henry showed that, supposing the co-efficient of solubility of a gas be determined in the case of pure gas, the co-efficient is not the same when the gas is mixed with other gases, but is directly proportional to the quantity of the gas present.

Thus, though the co-efficient of solubility of N_2O_3 in sulphuric acid is large, yet when this gas is mixed with large quantities of nitrogen and oxygen, that co-efficient is reduced very considerably; and taking ·01 per cent. as that contained in the gases passing into the air from a sulphuric acid chamber, the co-efficient of solubility is reduced to one ten-thousandth of its former value. From this it is evident that it is not practicable to prevent entirely the loss of nitre in the process of the manufacture of sulphuric acid by means of absorption.

It is quite possible that similar considerations may apply to a large number of cases where chemical combination of a loose kind takes place, and that in such cases also the extent to which the combination takes place is determined by some similar law of which we are at present ignorant, and dependent on the relative masses of the reacting substances. Thus, by far the greater part of the oxidation process of the sulphuric acid takes place in the first chamber; after that, the sulphurous acid is very slowly oxidised, and, in any case, partially escapes oxidation. We have indeed at the later stages of the process sulphurous acid, oxygen, and N_2O_3 mixed according to recent research, large quantities of sulphuric acid, and moisture in the form of vapour. If any process could be devised which would accelerate the rate of deposition of the sulphuric acid, this would no doubt accelerate the oxidation process, and render it more complete. Such considerations enter into various branches of the industries, where rule-of-thumb forms at present a very considerable element; and where chemical agency seems to have so little to do with the process, we cannot blame the manufacturer for adopting certain more or less empirical rules. But the reasonable mode of procedure would be to determine definitely what the action of mass is in such processes, and then it might be possible to work on more economical principles, and attain better results.

The recent papers by Messrs. Liechti and Suida tend to throw considerable light on the mordanting process from this point of view, and form a most valuable contribution to this branch of inquiry. Similar considerations will, no doubt, be found to bear in the ill-understood process of hardening mortars and cements, and in other similar cases. What is mainly wanted is, then, information of a definite character derived from the study especially of operations on a large scale; and such observations may fairly be expected from the technical chemist. Finally, to look at the subject in a more rigid manner, we should say that the course of a chemical reaction is determined by the degradation of energy which takes place, and is modified by the facilities which present themselves for bringing about contact between the molecules. Experiments have been made in this direction by Menschutkin, Bertholet, Guldberg, Waage and others, more especially on the latter of these two factors, and an example or two may make their method clear. If there be present p molecules of, say, ethyl alcohol, and q molecules of acetic acid, we write usually $p=q$, and give as the equation representing the reaction—

$$C_2H_5OH + CH_3CO_2H = CH_3CO_2C_2H_5 + OH_2.$$

The reaction in reality, however, does not attain completeness, and must be, from the dynamic point of view, looked upon as occurring between all the four substances taking part in it. The extent of the reaction and the point of equilibrium at which the relative amounts of the reagents cease to change will depend largely on influences external to chemical, especially on mass. Where $p=q$, 0·665 parts of acetic ether will be produced, where $q=2p$, 0·828 parts, and where $q=12p$, 0·933 parts. Menschutkin has made similar observations on a large number of alcohols, and achieved most valuable results. To take a second case.

On bringing together sulphate of barium and water in the relations of 1 in 500, and adding one molecule weight of potassium carbonate at 100°, until reaction came to a standstill, it was found that 0·176 of the barium sulphate had been transformed into carbonate. When two parts of potassium carbonate were used, the transformation took place to the extent of 0·395, and when three-and-a-half parts were used, to the extent of 0·719. We recognise here, then, the reaction in which barium sulphate, potassium carbonate, barium carbonate, and potassium sulphate enter in. If we increase the mass of any one of these four bodies, we influence the course and extent of the reaction. What would be the effect, now, of adding excess of potassium sulphate? We should expect that its influence would determine, in a great measure, the re-formation of barium sulphate; and, as a matter of fact, where the 0·25 parts of potassium sulphate were added, the amount of barium carbonate obtained, instead of being 0·395, was only 0·200; and where 0·5 of K_2SO_4 was introduced, only a trace of barium carbonate was found.

Gladstone found that the extent of the reaction which occurred between ferric salts and sulphocyanides depended on the masses used. I may also mention that Gladstone and Tribe found that there was a definite and simple relation between the concentration of the acid and the extent of its action.

In conclusion, I have to thank Dr. Hurter for one or two valuable suggestions in connection with this paper.

DISCUSSION.

Mr. Irwin: Anyone who had much to do with chemical operations would have often come across instances in which mass had a great deal to do with the result of those operations. One case especially had come under his notice in the extraction of benzol from coal-gas. Regarding this operation it was usual to say that the lighter boiling benzol might be extracted from the gas by absorption with a liquid of higher boiling-point, say xylol or cumol, in which it would dissolve. This statement, however, was only true in a sense, for it depended entirely upon the relative quantity of benzol in the gas to the xylol employed for its absorption. Take, for instance, Manchester gas, which contained about three gallons of benzol per 10,000 cubic feet. If a small quantity of this gas was allowed to bubble through several consecutive flasks containing xylol, all the benzol would leave the gas, and xylol in smaller quantity would take its place, and the former would become saturated with the latter substance. If, however, this gas were now passed through a similar number of flasks containing benzol in excess, the benzol would again gradually take the place of the xylol until the gas contained none of the latter, but was saturated with the former substance. Of course, this was really a physical operation, but it seemed to the speaker a good illustration of what Dr. Bailey had wished to indicate in his interesting discourse.

Mr. Thomson: Dr. Bailey mentioned as an example of the influence of mass, the action of silicic acid on potassium nitrate. He said when these were heated together the feeble silicic replaced the nitric acid. He could not make out whether he meant, by heating, actual fusion of the silica with the potassium nitrate, or whether the silica was boiled in a water solution of the nitrate. If he meant the former, the speaker could not see how the question of mass, as he applied it, had anything to do with the reaction. So far as he could judge, Dr. Bailey had given them no new facts in connection with the influence of mass on chemical action, nor had he suggested any new method of procedure by which one could measure the influence of mass so as to distinguish what was due to it, and what was due to the influences of temperature or other external agencies. With regard to his explanation of what mass had to do with mordanting of cloth, it did not seem to his mind satisfactory. Another suggestion which he gave as an example of the influence of mass was the production of hydrogen and calcium carbonate when steam was passed over anthracite coal covered with lime at a red heat. The coal decomposed the steam, forming hydrogen, carbonic acid, and carbonic oxide. The carbonic acid would, of course, combine with the lime if the temperature were not too high; and if it did so, it was evident that by simply raising the temperature higher the calcium carbonate would become dissociated and its carbonic acid liberated, whether the steam continued to pass over it or not. How this experiment illustrated Dr. Bailey's suggestions as to the action of mass on chemical action he could not see.

Mr. Dreyfus wished to compliment Dr. Bailey on the selection of his paper, and hoped that many more of a similar nature might be brought before the Society. He thought it was very desirable that many researches like the one investigated by Dr. Bailey should be extended to other substances. Dr. Bailey had stated that silica, in the presence of nitrate of soda and by the action of heat, would give nitric acid. He hardly thought that this action was to be attributed to the action of the mass, but could be easily explained by the well-known law, that a fixed acid, like silicic acid, displaced the more volatile acid, like nitric acid, by the action of heat. With regard to Messrs. Liechti and Suida's paper on Mordanting, referred to by Dr. Bailey, not having read it, he could not say what had been published in such paper about the action of mass in mordanting, but he could say that mordanting was a very simple operation, and that the results obtained with mordants depended entirely upon the saturation of such mordant. He might give as an example the following facts which came under his notice many years ago. When madder and garancine were used for dyeing reds, at that time a very strong mordant, about 12° T., was printed on the cloth and fixed in the usual way; it was then dyed up with a certain quantity of madder and soaped in the usual way. Unless such a mordant was thoroughly saturated with the colouring matter, the colour would come off in the soaping and give a very poor and uneven red; whereas if, instead of using such a strong mordant, a much weaker one was used, it took far less colouring matter to saturate it, and yet the red produced stood the soaping perfectly, and was deep, bright, and fast. It was his opinion that the mordant should form a saturated lake with the colouring matter in the case of dyeing with madder or alizarin, and if such a saturation had taken place the red produced would be a fast red. It should be the study of the colourist to see how far he could reduce his mordant in strength and still obtain this result.

Dr. Bailey said that what he wished more especially to do was, not to bring into notice the action of mass in a general way, but the necessity that existed for arriving at definite information as to its influence. If we bore in mind that such influence did take place we should be able to explain reactions which we came across in practical working, and which otherwise presented difficulties to us, and might probably be guided towards the realisation of reactions which otherwise were not attainable. He failed to see the force of Mr. Thomson's objection to the process of the New York Oxygen Company, as it seemed to him that considerations of temperature argued rather in the contrary direction to that which Mr. Thomson would require. Mr. Irwin's example was an interesting one, and no doubt numbers of such cases were constantly occurring unnoticed.

Meeting held in the College of Science, Wednesday, January 12, 1887.

PROF. P. P. BEDSON, D.SC., IN THE CHAIR.

DISCUSSION ON MR. RIDSDALE'S PAPER ON AN "APPARATUS FOR COLOUR TESTS," READ AT THE NOVEMBER MEETING, (POSTPONED FROM DECEMBER).

Mr. Ridsdale, at the invitation of the Chairman, added that his apparatus, though designed for use in a special process, was applicable to any colour-testing where the tints to be compared were not too deep. With reference to the speed of testing, he had mentioned in the paper that a test could be completed in 35 or 40 minutes; this, however, was by no means the possible rate of merely making comparisons. In winter time, by about three in the afternoon it was frequently too dark to compare colours, and after that time perhaps ten or a dozen samples would accumulate: in the morning these could all be started at the same time, and got ready for comparison in say 45 minutes, and then the mere comparison did not occupy more than half a minute each.

In answer to a question by Mr. John Pattinson, Mr. Ridsdale stated that the apparatus could be obtained from Mr. Robson, Linthorpe Road, Middlesborough.

DISCUSSION ON MR. JOHN PATTINSON'S PAPER ON "THE RATE AT WHICH BLEACHING-POWDER LOSES ITS AVAILABLE CHLORINE," READ AT THE NOVEMBER MEETING.

The Chairman asked whether the method of examining the powder in the casks was such as to ensure uniformity in the samples, or whether any stratification might have taken place in the casks, so that samples taken from different layers might have different compositions; also, whether the hygrometric state of the air in the cellar had been recorded? He remarked that the decomposition was obviously not all attributable to the effect of carbonic acid, but must be largely ascribed to the instability of the ClO group, which broke up, giving off either chlorine or oxygen.

Mr. Pattinson said that in packing the casks great care was taken to secure uniformity throughout; the casks were then laid on their sides, and samples taken by boring successively holes around the circumference of a circle on the end. He had not taken hygrometric observations, but as the casks were in a cellar, and the temperature was low, the air was probably pretty damp. With reference to an observation of the Chairman's, as to the disappearance of the chlorate being very remarkable, Mr. Pattinson said he had no explanation to offer, but the fact was well ascertained that while fresh bleach contained chlorate, old bleach frequently contained none. As to the low percentage of carbonic acid, which had been remarked on by Mr. Rennoldson when the paper was read, he had since repeated the determinations, and confirmed the results.

Mr. Stuart also remarked on the small amount of carbonic acid in the samples, and said that the results of Mr. Pattinson's experiments at higher temperatures would be awaited with interest by bleaching-powder manufacturers.

ON A GRAVIMETRIC METHOD OF ESTIMATING TANNINS.

BY HENRY R. PROCTER, F.C.S.

In the absence of any exact knowledge of the structure or equivalents of most of the tannins, it has long been desirable to have some method of determining by weight the actual quantity of matter in any tanning material capable of absorption by hide, independent of its nature or chemical constitution, or of any more or less arbitrary numerical factors. Some crude attempts at this were early made by Bell Stephens, by tanning thin pieces of raw hide in the liquor, and after drying, determining the gain of weight. No practical method could, however, be founded on this procedure, not only on account of the extreme slowness and imperfect character of the absorption under such conditions, but from difficulties connected with the uniform drying of the hide, and the large quantity required in proportion to the tannin present. A more hopeful effort in this direction was the "tan-tester" of Müntz and Ramspacher, which in various modifications consisted of a sort of small filter press, by means of which the liquid to be tested was forced through a piece of wet raw hide. By evaporating equal portions before and after this treatment, and weighing the residues, the loss of tannin was to be determined. In lieu of evaporation, a picnometrical determination was also employed, similar in principle to that of Hammer, and based upon the determinations which he had made of the specific gravity of solutions of gallotannic acid. Unfortunately, though admirable in principle and simple in execution, the method failed in practice, giving, in two careful sets of test-analyses undertaken to prove it by Mr. Evans and myself, discrepancies exceeding 30 per cent. of the total tannin present. These variations were caused on the one hand by the water present in the raw hide, which was necessarily of considerable thickness; and on the other by the great difficulty of ensuring the complete absorption of the tannin after a small volume of the solution had been passed through. A third source of error was also noted, which is common to all methods which employ hide or hide powder as an absorbent of tannin (and therefore both to Professor von Schroeder's modified Löwenthal method, and to the process I am about to describe), and which depends on the fact that hide is swollen by gallic and other acids, which are retained with considerable energy for the time, though probably expelled by tannin as the tanning process goes on. In the tan-tester, also, if much acid were present, the hide became so swollen that it was impervious to the liquids, and continued filtration was impossible.

Much attention has recently been devoted to the preparation of pure and very finely-divided hide powder, primarily for the absorption of tannin for the Löwenthal process; and among others, Mr. F. Simand, assistant at the Vienna *Versuchsstation für Lederindustrie*, has prepared very pure forms, both of hide power and of the gelatinous tissue of porous bones, which gave up to cold water nothing affecting permanganate in the Löwenthal test, and only a very minute portion of total soluble matter, not exceeding 36 milligrammes, from 5grms. This great freedom from soluble matter enabled Simand to make very fair determinations of the total absorbable matter of several tanning materials, but a great obstacle to success was the necessity of employing only very dilute tanning solutions to avoid hardening the hide powder and preventing further absorption. Early this year (*Dingl. Polyt. Jour.* 260, 564—568; *Chem. Soc. Jour.* Abstract, 1886, 1088), Messrs. Simand and Weiss published a very ingenious modification of their earlier method, by which this difficulty was completely overcome, and very much stronger infusions could be employed. Instead of adding the hide powder all at once, four or five small successive portions were employed at intervals of 6 or 8 hours, of which the earlier ones removed a large portion of the tannin, and so enabled the later ones to complete the absorption. Very satisfactory analyses are obtained by this method, and the principal drawbacks are the rather considerable time required and the consequent liability in hot weather to putrefactive action and increased solution of the hide powder.

It recently occurred to the writer that, building on the processes just described, a combination might be formed which should unite the rapidity of Müntz's with the exactness of Simand's method. The idea was that in filtration through a column of dry hide powder, the upper layers would absorb most of the tannin, and that from the large surface exposed a very complete and rapid separation would be obtained, and this in practice has proved to be the case. A very efficient apparatus for the purpose may be improvised from the lamp chimneys used in the common round-wicked German petroleum lamps, which are contracted just above the base of the flame, and cylindrical for the remainder of their length. A disc of cork is perforated with the cork-borer, and made slightly cup-shaped on its two faces. A piece of linen is then stretched over it, and it is pressed down the chimney till it rests on the contracted neck. 5grms. of hide powder are weighed into the tube, and, shaken down, will occupy a space of about 50cc. The tube is now cut off, allowing only length for the insertion of a cork, which may press slightly on the powder, as it contracts in volume when wet. This cork is perforated and hollowed like the first, and after being covered with linen is pressed into the tube. A short piece of quill-tubing fitting the hole in the cork, and which may be fitted by a second (notched) cork into a flask or broad bottle, completes the apparatus. If the liquid to be filtered be poured direct into the tube, it will be found in most cases that it will force a channel down one side of the glass, and so escape perfect absorption. This may be prevented by upward filtration; but to avoid this complication, the following mode may be adopted:—The filtering tube is inverted, broad end downwards, into a beaker of 100cc. capacity, which is filled with the liquid till it rises into the hide powder. If the tube be left an hour or two in this position, the hide powder will become gradually moistened for some distance; and if the tube be now reversed, and the enlarged end filled with the solution, the filtration will proceed evenly and steadily. In practice I have employed a solution of extract, etc., containing tannin equal to 10 or 12grms. per litre, though I do not know that this is the highest limit of strength admissible. Of this, 50cc. carefully filtered through paper, are evaporated at 100° C., to determine the total soluble solids. If total solids be determined by drying a portion of the original sample, the difference between the two determinations will give the insoluble, and this mode of procedure (suggested by Simand and Weiss) is preferable to a direct one, which from difficulty of filtration is often tedious or impossible. If now 50cc. of the hide filtrate be also evaporated, the residue of the hide powder, less a small correction for solubility amounting in the sample I am using to about 40 milligrammes, will be the "extractive" or soluble matter not tannin. I have found nickel crucibles very satisfactory for these evaporations, which proceed much more rapidly than from porcelain, though for ignitions they are inferior to platinum.

I have satisfied myself that the filtrates, made as described, are perfectly free from tannin, and tested by the Löwenthal method they show a lower result of "non-tannin" than those by any other method of absorption with which I am acquainted. At the same time it is obvious that tanning extracts, and even the purest commercial tannins, contain matters which are partially removed by the filter, probably as sand, and other chemically neutral filters will remove more or less of certain colouring matters and salts. Thus, in testing a sample of Schering's tannin ph. gr. (recommended by Von Schroeder as the purest German tannin), the first 5cc. were equivalent to only 0·5cc. of permanganate (1grm. per litre), while 5cc. taken after running about 70cc., required 2·3cc. If this were reckoned out as gallotannic acid it would amount to from 1·3 per cent. to 4·3 per cent. of the total employed, but it was shown by testing with ammonia sulphate of copper that there was probably none, and, at most, much less than 1 per cent. of the original tannin present, and the reaction was due to gallic acid. Other tanning materials which do not yield gallic acid, still contain other bodies which similarly affect the results. As I have already stated, gallic acid is pretty freely absorbed by hide, a 1 per cent. solution losing 78 per cent. of the total. This unfortunate peculiarity completely condemns hide powder for rigid scientific work where gallic acid is present, and makes it desirable in the analyses of such materials as sumach, galls, and myrabolanes to employ the Löwenthal method with precipitation with gelatin and salt, using the proportions advised by Mr. Bertram Hunt (this Journal, *1885*, 266). I am in hopes, however, of overcoming the difficulty, either by some method of removing the gallic acid or preventing its absorption by the hide.

In order to ascertain whether neutral bodies, such as are found in tanning materials, are withdrawn from solution by the hide filter, experiments were made with glucose and dextrin. 50cc. of a solution of commercial glucose, containing 0·6grm. of the air-dry substance left 0·506grm. after drying at 100° C. An equal quantity, after passing through the hide filter, left 0·594grm., thus having apparently taken up 0·088grm. from the hide. As only about 0·04—0·05grm. would have been dissolved under similar circumstances by distilled water, it seems as if glucose had the power of increasing the solubility of hide; a point deserving investigation, both from the analytical and the technical standpoints; since glucose has been frequently used for the removal of lime from hide, for which purpose any solvent power on the hide itself would be fatally objectionable.

Dextrin appears quite indifferent, the gain of weight in passing through the hide filter being 0·045grm., or practically the same as with distilled water.

In order to apply either this process, or that of Simand and Weiss, successfully to the analysis of solid materials, much stronger infusions are required than for the Löwenthal method, and it becomes a difficult problem to obtain them, and, at the same time, to secure complete exhaustion. To accomplish this, Messrs. Eitner, Simand, Meerkatz, and Weiss* have been jointly investigating the application of the principle so often employed in the estimation of fats—viz., that of continuous exhaustion by the same body of liquid, by aid of the return-flow condenser. They have proved (what a tanner would scarcely, *à priori*, have expected) that even materials so easily changeable as sumach and valonia suffered no material loss of tannin absorbable by hide, even by prolonged boiling, though the colour was decidedly darkened. Their experiments do not seem to have embraced gambier, which Hunt† found to lose considerably by boiling in contact with air. Having satisfied themselves that prolonged boiling was admissible, they have constructed an apparatus similar in principle, though differing in detail, from the well-known Soxhlet's tube, which they find to work satisfactorily.

Since distilled water is neither expensive or poisonous, like the more volatile fluids employed for fats, it is questionable whether, for any small number of analyses, the use of so comparatively complicated and expensive an apparatus is either necessary or desirable, though for an institution like the Vienna Leather Industry Research Station it is undoubtedly very convenient, enabling many exhaustions to go on at once with little attention. Probably excellent results would be obtained by boiling the sample for, say, half-an-hour, with as small a quantity of water as practicable, draining off the strong liquor, and completing the exhaustion with hot water, which should be evaporated to small bulk in a flask, and added to the strong liquor before making up the required quantity. This would have the incidental advantage of avoiding prolonged boiling of the greater part of the tannin. A convenient and simple apparatus for the purpose might be improvised by fitting a rather wide-tubed funnel into a flask with a cork, and slipping a smaller one inside it containing the tanning material, in a filter. The flask being placed over the gas, evaporation and washing the residue might go on simultaneously, while the material would be retained at boiling temperature by the escaping steam.

M. Eitner and his colleagues give a series of analyses in the paper referred to, both by the Löwenthal and the hide powder methods, which show that even for the same material there is in most cases no constant relation between the permanganate value and the absorbable tannin, the relation being affected even by the age and growth of the sample. This is only what might have been expected, when we consider that most tanning materials are natural mixtures containing more than one tannin in varying proportions. On this ground Eitner has entirely discontinued the use of the Löwenthal method in the Vienna Laboratory in favour of the Simand-Weiss. Until, however, some satisfactory plan is hit upon of separating the gallic acid, neither this nor the modification I have described can be regarded as wholly satisfactory, at least for such materials as are apt to contain this acid.

† This Journal, **1885**, 263.

ON THE ESTIMATION OF SULPHUR IN PYRITES.

BY G. LUNGE.

In the *Analyst*, November, 1886, p. 209, Mr. J. C. Welch publishes a process for assaying iron-pyrites for sulphur, available for sulphuric-acid manufacture, for which he claims advantages in speed and accuracy over that process which is generally associated with my name. I have no intention of entering into a controversy upon the point, whether Mr. Welch's process is really "cleaner and nicer," and altogether less troublesome than mine, as I think that may be safely left to the judgment of every one for himself. As far as the greater rapidity of work is concerned, I fail to see how Mr. Welch's process could be carried out in less time than mine, even assuming the necessary apparatus to have been put up, and the oxygen to have been prepared beforehand, failing which conditions, that process must evidently take a very long time indeed. But I should not trouble the Society with any utterance on that process, if Mr. Welch did not represent it as more *accurate* than a process which he calls mine, but with which I have nothing to do, and that upon the strength of some experiments which are altogether inconclusive. This error I feel bound to point out.

Mr. Welch says: "Professor Lunge claims that his method, by means of the decomposition of the pyrites by strong nitric acid, is the best for the estimation of available sulphur, as any lead sulphide which might be present, as galena, would be oxidised to insoluble sulphate of lead." In order to refute this he procured some lead sulphide, "sold as pure," which he treated with fuming nitric acid, whereupon he found in the filtrate from 1·263 to 2·389 per cent. of sulphur, which the nitric acid must have taken up from the lead sulphide. It is not clear whether the percentage is calculated upon 100 lead sulphide or 100 total sulphur, but this is really not very important, as he did not prove that the sulphur really came from PbS, not from some of the impurities adhering to the article "sold as pure." We shall see presently that even pure PbS would probably have yielded some, but very little, sulphur.

In another experiment Mr. Welch treated 1grm. of pure lead sulphide, prepared by himself, from which he obtained by the nitric acid treatment barium sulphate equal to 1·918 per cent. of sulphur. But according to his own statement, he obtained from 1grm. of the same sulphide by his process of ignition in oxygen 1·390grms. of "lead sulphate," whilst 1grm. of lead sulphide theoretically yields 1·293grms. of sulphate, according to Mr. Welch's, but in reality only 1·268 (Pb = 206·39, O = 15·96, S = 31·98). Hence this "pure" lead sulphide must have been very impure indeed, even if we assume that 1·390 is a misprint for 1·290. Since presumably the sulphur of any other metals present in his "pure" lead sulphide would be dissolved in the treatment, Mr. Welch's experiments are refuted by his own figures, and most certainly cannot claim to have shown me to have been in error.

But the matter does not end here, for Mr. Welch has made some further altogether unaccountable mistakes. In the first instance he chooses to associate a method with my name which is the very method I opposed when bringing out my own. This was done at a meeting of the Newcastle Chemical Society, in December, 1885, and this opposition was repeated in my "Manufacture of Sulphuric Acid and Alkali," vol. i. p. 102, from which, probably most chemists have taken my method, which has subsequently been adopted, after careful examination, by the German Association of Alkali Makers, as binding upon buyer and seller, and which is hence repeated in the "Alkali-Makers' Pocket-Book," English edition by Lunge and Hurter. I say there: "The solution has frequently been made, by Fresenius' prescription, by means of red fuming nitric acid, which it is sometimes difficult to obtain free from sulphuric acid, and which is unpleasant to handle. . . . The author has always found the best, safest, and cheapest way to be that by aqua regia, made from one part of fuming hydrochloric acid and three or four parts of nitric acid of sp. gr. 1·36 to 1·4." Later on I made a special study of the action of acids on pyrites, which completely confirmed and even enlarged the above; and as I am not aware of my investigation having been more than quite cursorily reported in English (it was printed in the *Chemische Industrie*, 1882, p. 76), I beg leave to quote my results, as obtained, with various descriptions of iron pyrites :—

(*a*) Nitric acid of sp. gr. 1·48, yellow, and strongly fuming, does not act at all in the cold, and but slowly at the heat of a water-bath; the decomposition is imperfect.

(*b*) Nitric acid of sp. gr. 1·465, yellow, strongly fuming behaves exactly like the former.

(*c*) Nitric acid of sp. gr. 1·42, chemically pure, colourless, after a few seconds causes a violent reaction without any external heat being applied; much heat is given off, and in a few minutes the decomposition is complete, no sulphur being separated as such.

(*d*) Nitric acid of sp. gr. 1·40, yellow, behaves just like the former.

(*e*) A mixture of three parts strong hydrochloric acid and one part of nitric acid of sp. gr. 1·42 does not act in the cold; on the water-bath there is soon a reaction, but the decomposition takes a long time.

(*f*) A mixture of one part strong hydrochloric acid and three parts nitric acid of sp. gr. 1·42 causes a strong reaction after a few seconds, with considerable evolution of heat, and after a few minutes the decomposition is complete, without any separation of sulphur.

This last mixture, which is identical with that mentioned in my book, was thus found to be the very best; next to it comes nitric acid of sp. gr. 1·40 to 1·42, which, however, necessitates several times evaporating with hydrochloric acid; *"fuming" nitric acid, which is imputed to me by Mr. Welch as being part of "my process," was found by me the least suitable of all.*

Hence, if Mr. Welch really wanted to oppose my process, he ought not to have made his experiments with fuming nitric acid, but with the mixture prescribed by me, the decomposing power of which for lead sulphate would evidently differ from that of nitric acid by itself. This alone would dispose of his experiments as being beside the mark, but there is more positive argument against them as well.

My method of assaying pyrites, as described in my Alkali treatises, had been attacked by Fresenius, as not possessing sufficient accuracy. This led me to re-investigate the whole matter in a fundamental manner, and to send my paper to Fresenius himself, who requested me to make some further experiments, and then published the whole in his *Zeitschrift für Analytische Chemie*, 1880, vol. xix. p. 419—431, without a word of opposition, thus tacitly acknowledging the correctness of my work, which, indeed, has never been impugned since that time. One of the subjects mentioned by me in the appendix, as tested from Fresenius' suggestion, was the action of the liquid on lead sulphate. I did not, however, proceed in the manner preferred by Mr. Welch—that is, working under conditions which never occur in practice—namely, acting on "pure" lead sulphide with fuming nitric acid, but I made my experiments to conform exactly with the conditions of an ordinary pyrites test—viz., adding some lead sulphate to a solution of ferric sulphate, precisely corresponding to that which is obtained in my process when acting on iron pyrites, evaporating to dryness, boiling with very dilute hydrochloric acid, filtering, and weighing the undissolved lead sulphate. I thus proved that so little lead sulphate entered in solution, that the error caused by it in an ordinary pyrites test would not have exceeded a few hundredths of a per cent. of sulphur.

In consequence of Mr. Welch's attack I wished to once more investigate this matter; but in order to preserve all possible freedom from bias I requested one of my demonstrators, Mr. Mohler, to perform the experiments in question from my directions. A solution was made of 2grms. crystallised ferrous sulphate = 0·2302grm. sulphur. To this was added 0·7grm. pure sulphuric acid, corresponding to 0·2286grm. sulphur. The liquid, containing 0·4588grm. sulphur, was heated with 10cc. of pure concentrated nitric acid, in order to oxidise the ferrous sulphate to ferric sulphate. To this was added about one decigram of pure lead sulphate (prepared by precipitation, thorough washing, and drying at 100° for several hours), exactly weighed (0·1020grm. in one case, 0·0876grm. in another case). The whole was evaporated in the water-bath till all the nitric acid had been driven away, and now in every way corresponded to the condition in which an ordinary pyrites test would be at the end of the decomposition, starting from one grm. of 45 per cent. pyrites, containing a few per cent. of galena. When the whole had been brought to dryness, it was heated up to 90° or 100° with 100cc. of water and 1cc. of concentrated hydrochloric acid, kept hot for 10 minutes, filtered, and washed till there was no more acid reaction whatever. The undissolved lead sulphate was again dried under exactly the same conditions as before (the filter-paper having been previously treated in the same way), and the weight determined. The residue in the first case amounted to 0·0979grm., in the other to 0·0820grm. This means that in the first case 0·0041grm., in the second 0·0056grm. $PbSO_4$ had been dissolved. The mean is 0·005grm. $PbSO_4$, or 0·0005grm. S. In other words, the quantity of lead sulphate dissolved was so slight that the sulphur imported from it into the pyrites test would not influence the percentage return to a greater extent than 0·05 per cent. of sulphur—a quantity altogether vanishing beside the usual discrepancies of testing pyrites, which even in the most skilful hands, and with the very best analytical methods, often amount to 0·25 per cent.

I have thus proved the following facts :—

(1.) Mr. Welch's experiments were made with impure lead sulphide, and are hence inconclusive.

(2.) They would have been so, even if the lead sulphide had been pure, since Mr. Welch worked under conditions expressly repudiated by me, and in no possible way representing *my* process.

(3.) Positive experiments, made by me in 1880, and now by Mr. Mohler, prove that in the conditions actually present in testing pyrites—viz., in solutions containing exactly as much iron, sulphuric acid, hydrochloric acid, and water as are formed in my testing process, the solubility of lead sulphate is so slight as to make it unnecessary to take it into account for all practical purposes.

Meeting held Wednesday, February 9, at the College of Science.

PROFESSOR BEDSON IN THE CHAIR.

ON NEW OR PERFECTED METHODS FOR THE DETECTION AND ESTIMATION OF ORGANIC BODIES, BASED UPON THEIR OXIDATION BY POTASSIUM PERMANGANATE.

BY JOHN HENRY SMITH, PH.D. (ZURICH),
Associate of the Royal College of Science, Dublin.

PART I.

The utility of potassium permanganate as a reagent in both qualitative and quantitative analysis has long been recognised. The ease with which titrations in volumetric analysis are performed, the speed with which these are accomplished in the case of potassium permanganate, and the decided colouration of the titrated solution, even when highly diluted, in the presence of the smallest excess of the reagent, combine to render this body a particular favourite with chemists. Still, the best of friends has his faults, and $KMnO_4$ is no exception. Certain well-known restrictions must always be observed in its employment, and many substances upon which it is known to exert a greater or less oxidising action have been hitherto subjected to the same only as a qualitative test, owing to the incompleteness of the action, or to the formation of intermediate manganese compounds, whose composition has been only imperfectly investigated, but is generally considered to be of a variable character.

To such a class belong organic bodies generally, oxalic acid being the only one which has surrendered itself to complete oxidation, under the ordinary conditions of working. I know of no other organic body which has been completely oxidised by $KMnO_4$ under conditions which would allow of the quantity of oxygen absorbed in the reaction being even approximately estimated. Several attempts have been made, I am aware, but the general conclusion derived from them has been that the oxidation is incomplete, and too variable, even when working under conditions as equable as possible, to found even a relative method of estimation upon the reaction. W. Lenz[*] succeeded in oxidising grape sugar to the extent of 54 per cent., and glycerin to 24 per cent.; but he states that the results vary with the quantity of permanganate solution first added, under otherwise exactly the same conditions.[†] The same conclusion had long been arrived at, in regard to the employment of this reagent for the estimation of the organic matter in potable water.

I have carefully investigated the deportment of potassium permanganate while undergoing the process of reduction, have ascertained the cause of the fluctuations in the recorded results, and have succeeded in nullifying the same, thereby being enabled to found certain reliable methods, generally applicable to the detection and estimation of organic bodies.

Considering the large extent to which such bodies enter into English chemical industry, and the importance of possessing more accurate and rapid methods for their valuation, I need hardly apologise for bringing the results of my experiments before the notice of this Society.

It will probably prove most interesting and instructive, if I adhere generally to the order of the experiments which prevailed in the course of the investigation.

DIRECT TITRATIONS WITH $KMnO_4$.

No results having a practical bearing were obtained from the titration of organic bodies in the usual manner; the oxidation was incomplete in the case of every body examined, excepting, of course, oxalic acid, and not even sufficiently constant to form any reliable method of comparison.

The chief value of these experiments lies, therefore, in their corroboration of the results previously obtained by other experimenters, and in their more emphatic demonstration of the utter untrustworthiness of the permanganate method of estimating the organic matter in drinking water, even as a comparative method, and working under conditions generally assumed to be similar; and assuming, further, that the organic impurity present is of the same nature in the samples under comparison. Some of the general results obtained are of sufficient importance, however, to be quoted here.

In alkaline solutions, a direct titration cannot be effected at any temperature, on account of the production of soluble green salts of manganic acid, or of insoluble manganese compounds.

In exactly neutral solutions, organic bodies, with few exceptions, are incapable of decolourising a drop of permanganate solution, even at a temperature approaching ebulition. Even oxalic acid remains unoxidised when exactly neutralised. Tannin is, however, an exception to the rule. It may be titrated to the extent of about 62 per cent. of the total oxidation possible at 100° C., before any manganese is precipitated; but the dark yellow colour which the solution assumes renders it impracticable to employ this reaction as a quantitative one. Tartaric and citric acids may also be titrated to a slight extent in boiling neutral solutions, the former to 1 per cent., and the latter to 2½ per cent. of the total oxidation. This is probably due to the slight solubility of the manganese precipitate in exactly neutral solutions, which we know is the case with MnO_2.

The behaviour of organic bodies in sulphuric acid solutions, when acted on by $KMnO_4$, is very varied. As a rule, the oxidation proceeds so slowly in the cold, that a protracted waiting is required for the discolouration of each drop of permanganate solution, extending frequently to hours. Even oxalic acid is no exception to this rule. With citric acid (which may be titrated as rapidly as oxalic acid in hot solutions), twenty minutes were required to decolourise 0·2cc. of normal $KMnO_4$ (1cc. = 0·01grm. Fe).

As the temperature rises, the speed of decolouration increases. Most bodies, however, even at the boiling temperature, are exceedingly slow in reducing traces of permanganate, and in *all* cases which I have examined—excluding oxalic acid—a point arrives in the titration, before the oxidation is perfect, at which a brown manganese precipitate is formed. Although I am persuaded that there is a theoretical point in the reaction corresponding to the appearance of this precipitate—apart from the tediousness of the operation—I have never found the observed period sufficiently constant to found a process of estimation upon the reaction. The chief reason for this irregularity is, that as the theoretical point is approached the formation of the precipitate becomes easier, and its solution more difficult; and two drops of permanganate added at once, or a slight lowering of temperature, might produce it permanently, where two consecutive drops, or a constant high temperature, would have prevented its formation.

---

[*] Zeits. Anal. Chem. 21, pp. 34—41.

[†] Unfortunately, I have neither been able to consult the original paper for these conditions, nor to obtain them from the author, to whom I wrote.

With tannin, which can be titrated with great rapidity, the precipitate occurs after about 66 per cent. of the total oxidation, corresponding nearly to the absorption of 16 atoms of oxygen per molecule. With tartaric and citric acids, which may also be titrated rapidly at the boiling temperature, precipitation occurs when about 69 and 73 per cent., respectively, of the oxygen required for perfect oxidation has been absorbed; corresponding to an absorption of 3½ and 6½ atoms of oxygen, respectively, per molecule. A precipitate was formed with formic acid after addition of 4 per cent. of the total oxygen, this possibly being due to impurity. With acetic acid, glycerin, cane sugar, alcohol, ether, and probably the vast majority of organic bodies, the precipitate is formed on the addition of a few drops of $KMnO_4$ solution, after more or less prolonged boiling.

The amount of free acid present does not make that difference in the speed of oxidation which might be expected. Indeed, oxalic, tartaric, and citric acids may be titrated with comparative ease, at a high temperature, in virtue of their own acidity, until this has been neutralised, when the action stops. The equation—$K_2Mn_2O_8 + 8H_2C_2O_4 = K_2C_2O_4 + 2MnC_2O_4 + 10CO_2 + 8H_2O$ represents the oxidation of oxalic acid until it is rendered neutral. It is seen that $\frac{5}{8}$ths or 62·5 per cent. of the total oxidation has been effected at this stage. In several experiments 64 per cent. could be oxidised before manganese was precipitated. The excess was probably due to a trace of acid in the permanganate. I endeavoured to establish a method for estimating the acidity or alkalinity of $KMnO_4$ solutions, by oxidising standard oxalic acid therewith to about 50 per cent., and determining the free acid remaining in the solution with standard KHO. In this endeavour I was not successful. The point at which the potash commences to attack the manganous oxalate is not sufficiently definite, either with litmus or phenolphthalein as indicator (methyl-orange could not be employed), in boiling or in cold solutions. No better results were obtained by adding excess of KHO, and titrating back.

In the titration of tartaric and citric acids, without addition of external acid, three cases are possible. Either the oxatyl radicals themselves, or another part of the acid may be first oxidised, the COOH in the latter case being employed in neutralising the K_2O and MnO liberated, or both these actions may occur. The equation already given represents the first case; the second may be represented thus:—$K_2Mn_2O_8 + 3H_2C_2O_4 = K_2C_2O_4 + 2MnC_2O_4 + 3H_2O + O_5$. Here we find that acidity equivalent to 3 molecules of oxalic acid is sufficient for an oxidation demanding 5 atoms of oxygen, while an equivalent of 8 molecules was necessary in the former case. Each oxatyl radical in an organic acid would, in the former case, be equivalent to an oxidation requiring $\frac{5}{16}$ths of an atom of oxygen, and in the latter case to one requiring $\frac{5}{6}$ths of an atom of oxygen. As there are two of these radicals in, and 5 atoms of oxygen are required for, each molecule of tartaric acid, the former case would represent an oxidation equivalent to $\frac{5}{16} \times \frac{2}{5} = 12{\cdot}5$ per cent., the latter one of $\frac{5}{6} \times \frac{2}{5} = 33{\cdot}3$ per cent. of the total oxidation possible. If we assume that the whole body is being equally oxidised, then the oxidation will be $\frac{12{\cdot}5 + 33{\cdot}3 \times 4}{5} = 29{\cdot}2$ per cent. of the total. But we have seen that only 69 per cent. of the total oxidation is effected in the presence of a large excess of acid in direct titration. If we include the oxidation of the oxatyl radicals in the 69 per cent., as we have reason for doing, the oxidation becomes $\frac{12{\cdot}5 \times 20 + 33{\cdot}3 \times 49}{63} = 27{\cdot}3$ per cent. The amount oxidised in a direct titration was found to be 29·7 per cent. of the total. If we allow for the small amount of acid in the sample of $KMnO_4$ employed, and the 1 per cent. capable of being oxidised in a neutral solution, the result is almost identical with the last-mentioned oxidation.

In working out these quantities for citric acid, we obtain $\frac{5}{18} \times \frac{3}{8} = 10{\cdot}4$ per cent. for the oxidation of the COOH radicals alone, $\frac{5}{6} \times \frac{3}{9} = 27{\cdot}8$ per cent. for the oxidation of the other portions of the body, and $\frac{10{\cdot}4 \times 16{\cdot}66 + 27{\cdot}8 \times 56{\cdot}34}{73} = 23{\cdot}8$ per cent. for the oxidation simultaneously of those radicals which are capable of oxidation by direct titration. In point of fact, 14·5 per cent. was oxidised before manganese was precipitated, showing that the oxatyl radicals in this case are oxidised much quicker than the rest of the body. Indeed, if we allow for the acidity of the $KMnO_4$, and deduct the 2 per cent. capable of being titrated in a neutral solution, it becomes doubtful if anything more than the oxatyl radicals are oxidised. Thus, to numbers apparently arbitrary, important meanings may be attached.

In the direct titration of oxalic, tartaric, and citric acids, I constantly observed that the speed of oxidation rapidly increased as the action proceeded; the first few drops of permanganate being exceedingly tardy in their reduction, even in warm solutions. The cause of the increased speed I traced to the presence of the manganous salt formed during the action, which salt, as we shall see later on, has the power of reducing the permanganate, thus accelerating the oxidation. It may be looked upon as a carrier of oxygen in the same light as ferric, aluminic, and other chlorides have been shown to act as carriers of chlorine to organic bodies by Page;* these salts themselves remaining unaltered. By taking advantage of this action, and adding a little manganous sulphate to the acidified solution, I found it possible to titrate fairly rapidly from the commencement, in comparatively cold solutions.

I was disappointed in the application of this result to the titration of those organic bodies which had proved so obstinate of reduction. On the addition of $MnSO_4$ to their solutions, they did not prove more amicable to titration, although the brown manganese precipitate was formed much sooner than in the absence of the manganese salt.

The direct titration experiments having failed to yield a reliable method of analysis, I was led next to investigate the action of excess of permanganate upon organic solutions. Before proceeding with this subject, it will be advisable to refer somewhat fully to the brown manganese precipitate, which is always formed in presence of excess of $KMnO_4$, and which we also found to be a final product in the direct titration of organic bodies.

ON THE NATURE OF THE MANGANESE PRECIPITATE.

With the ultimate composition of the precipitate I was not immediately concerned, but rather with the state of oxidation of the manganese it contained. Lunge and the author,† in examining the action of potassium permanganate on sodium thiosulphate in neutral and alkaline solutions, assumed that the precipitated manganese existed in the state of dioxide; and their assumption was borne out by the fact that the theoretical amount of permanganate was not absorbed until excess had been added to satisfy the following equation:—$3Na_2S_2O_3 + 4K_2Mn_2O_8 + H_2O = 3Na_2SO_4 + 3K_2SO_4 + 2KHO + 8MnO_2$—*i.e.*, five-thirds the amount which would be required if the $KMnO_4$ were completely reduced to the form of MnO.

† This Journal, 1883, 163.

Morawski and Stingl* have attached the general formula $KH_3Mn_4O_{10}$ to the precipitate. Hönig and Zatzek† give $KH_3Mn_3O_8$ as its composition, in the case of the oxidation of $Na_2S_2O_3$ in alkaline solution. M. Gläser‡ states that K_2CO_3 enters into its composition under the conditions named, and confirms Morawski's formula in the case of the oxidation of $Na_2S_2O_3$ in neutral solutions. Hönig and Zatzek,§ replying to Gläser, question whether the precipitate can be represented by a constant formula, and state that they as well as other authors have been unsuccessful in analysing it, as it becomes altered in the process of washing, retaining foreign matter. Although such diverse opinions are held concerning the nature of the precipitate, it will be observed that in both the above formulæ the manganese exists as MnO_2. In all my experiments this result has been confirmed, and that whether the precipitation occurs in neutral, alkaline, or acid solutions.

F. Jones,‖ however, in treating of the action of hydrogen, ammonia, phosphine, arsine, stibine, manganese chloride, and manganese sulphate on potassium permanganate, finds the precipitated manganese, in each case, in the state of Mn_2O_3, never as MnO_2. Now Jones effects all his analyses by weighing the precipitate, dried either on the water-bath or over sulphuric acid ; then reducing it with hydrogen, or igniting in air, and again weighing. He has evidently assumed the precipitate to be a pure hydrated oxide of manganese, and does not seem to have examined it carefully for foreign constituents. The percentage of manganese which he finds in the precipitate dried on the water-bath is generally less than, but approximates 62·5, which corresponds to the formula $Mn_2O_3 + H_2O$. But in MnO_2 the percentage of manganese is 63·2 ; is it not probable, therefore, he has been dealing with an impure peroxide? It is true he estimates the water in the dried precipitate in two cases, and finds it to agree with the above hydrate ; but, again, the loss in weight would have been the same had the precipitate been MnO_2, and the heat employed barely sufficient to reduce it wholly to Mn_3O_4.

Christensen¶ has shown that pure Mn_2O_3 is so attacked by dilute nitric or sulphuric acid that *precisely* one-half of the manganese passes into solution, the other half remaining as insoluble MnO_2. This evidence disproves Jones' conclusions, therefore, with regard to the nature of the precipitate in acid solutions. Although it has not come within my province to examine the precipitate carefully for foreign matter, my experience corroborates that of previous authors in ascribing to it the property of retaining, at least under certain conditions, constituents of the solution in which it is formed, and this not only in neutral and alkaline solutions, but also in acid ones. With the state of oxidation of the precipitated manganese, however, I was most intimately concerned, and I shall now quote a few experiments which directly refute the conclusions of Jones, although abundant indirect evidence in confirmation of the manganese existing in the state of MnO_2 will be found throughout this investigation.

Five separate solutions, each containing 50cc. of pure oxalic acid solution, to which equal amounts of dilute sulphuric had been added, were exactly titrated with permanganate in the usual manner. To the 1st, additional $KMnO_4$ was added, in amount equal to exactly two-thirds of the quantity required for exact titration. The 2nd solution was exactly neutralised with NaHO, and the same amount of additional $KMnO_4$ added. The 3rd, 4th, and 5th solutions were made decidedly and equally alkaline with NaHO, K_2CO_3, and $KHCO_3$ respectively, and additional $KMnO_4$ immediately added as before. All 5 solutions, made up to 250cc., were heated on the water-bath for about 2 hours, and the precipitate allowed to settle. It will be seen that the $KMnO_4$ added was just sufficient in each case to satisfy the equation—$3MnO + K_2Mn_2O_8 = 5MnO_2 + K_2O$; the amount of $KMnO_4$ reduced being a measure of the MnO oxidised. Now the neutral solution had become quite colourless, showing that the manganese had been quantitatively oxidised and reduced respectively to the state of peroxide. The other four solutions were still coloured. After the precipitates had thoroughly subsided, the solutions were carefully decanted, acidified with H_2SO_4 where alkaline, and titrated back with standard $FeSO_4$ solution. The following results were obtained :—

No. of Experiment—	1	2	3	4	5
State of solution	H_2SO_4	neutral	NaHO	K_2CO_3	$KHCO_3$
% $KMnO_4$ reduced	99·85	100	96·0	96·8	97·0

If Mn_2O_3 had been precipitated, only 37·5 per cent. of the $KMnO_4$ would have been reduced, as shown by a comparison of the two following equations :—

$$3 \text{ times } K_2Mn_2O_8 + 8MnO = 5Mn_2O_3 + K_2O.$$

$$8 \text{ ,, } \quad K_2Mn_2O_8 + 3MnO = 5MnO_2 + K_2O.$$

That the reduction was not so complete in the alkaline solutions as in the acid solution may be partly accounted for by the slight oxidation of the manganese precipitates by the atmosphere, before the addition of the $KMnO_4$.

Now Jones considers that even if MnO_2 be precipitated, it is at once reduced to Mn_2O_3, oxygen being liberated. I shall treat of the evolution of oxygen in another part of this paper ; it will be sufficient to state that in the case of the neutral and alkaline solutions above referred to no oxygen is generated, while in the acid solution, under the conditions given, the loss is so slight that it need not be taken into consideration. In another experiment in acid solution, but merely warmed on the bath for five minutes, (Experiment 6), 98·5 per cent. of the $KMnO_4$ was found to have been reduced. We thus see that $KMnO_4$ is capable of oxidising $MnSO_4$ practically completely to MnO_2, even when the two bodies are present in only the theoretical proportions, and that whether the solution be acid, alkaline, or neutral. I shall refer later on to the application of these results to the estimation of manganese in manganous salts.

It is worthy of remark, that although all the precipitates contained Mn in the form of MnO_2, they were different in appearance, from which we might conclude that their absolute composition varied. That formed in the neutral solution was very bulky, and brown in colour ; those in the K_2CO_3 and H_2SO_4 solutions were very small in bulk ; while the others were of medium bulk. The precipitate in the acid solution was almost black ; the others were more or less brown.

It still remained to be proved that the precipitates formed with insufficient $KMnO_4$ are in the form of MnO_2. In order to confirm Christensen's experiments,** 50cc. of pure acidified oxalic acid solution were exactly titrated with $KMnO_4$, and additional permanganate added equivalent to 83·3 per cent. of

** *Loc. cit.*

the total quantity required to convert the whole of the manganese salt into MnO_2—*i.e.*, as we have seen, 45·8 per cent. in excess of the quantity required to convert it into Mn_2O_3, according to Jones's statement. After heating a few minutes the solution became quite colourless; it was then filtered, and K_2CO_3 added to the filtrate, when a considerable precipitate of $MnCO_3$ occurred. From this we learn conclusively that MnO is not oxidised to Mn_2O_3, but to MnO_2 in acid solutions.

The same experiment was performed in a solution nearly neutralised before the addition of the excess of $KMnO_4$, but sufficiently acid, I thought, to prevent the precipitation of MnH_2O_2, or the solution of the MnO_2 formed. The filtrate gave a slight precipitate with NaHO, which turned brown, but it was evident that some manganous hydrate had been precipitated with the MnO_2. Now if it existed in combination with MnO_2 as Mn_2O_3 we would not expect it to be oxidised by atmospheric oxygen. To prove whether this was the case I allowed the precipitate to remain on the filter for two hours, but otherwise no means were adopted to admit excess of air. At the end of that time the precipitate was dissolved in 50cc. of standard $FeSO_4$ solution, and titrated back with $KMnO_4$. I found that additional 2·1 per cent. (Experiment 7) of the original $MnSO_4$ had been oxidised to MnO_2. If, therefore, Mn_2O_3 were a stable body in neutral solutions, how could it be oxidised by the air, and more especially in the presence of a large excess of MnO_2?

It is generally accepted* that MnH_2O_2 is oxidised in moist air to $Mn_2O_2(OH)_2$, but my experiments prove that manganous hydrate is oxidised continuously in the moist state by atmospheric oxygen to dioxide both in neutral and alkaline solutions, and I am inclined to the opinion expressed by Hermann† and Rose‡ that the so-called sesquioxide, at least in the moist state, is not of similar constitution to Fe_2O_3, but a mere mixture of $MnO.MnO_2$.

In similar experiments to those just recorded, but in solutions made alkaline with NaHO, the following results were obtained; in each case the precipitate having been exposed two hours on the filter before being dissolved :—

No. of Experiment—	8	9	10	11
% $KMnO_4$ added of amount required for complete oxidation to MnO_2................	33·3	50·0	66·6	83·3
% oxidised by atmosphere ..	3·9	6·9	4·2	3·3

As we have already seen, 37·5 per cent. excess $KMnO_4$ would have been sufficient to convert all the MnO into Mn_2O_3. As a matter of fact there is no greater tendency to oxidation shown when less $KMnO_4$ has been added than when this amount has been far exceeded. Although the addition of $KMnO_4$ was performed as expeditiously as possible, it might be objected that the oxidation recorded had been effected between the addition of the alkali and the $KMnO_4$. To make quite certain upon this point the following alterations in the manipulation were made. Instead of the titrated oxalic acid, 25cc. of a solution of pure $MnSO_4$, whose strength had been accurately determined, were employed, and run in by means of a pipette at the bottom of the warm caustic soda solution, to which the requisite amount of $KMnO_4$ had previously been added. Under these conditions the action of the $KMnO_4$ must precede that of the atmosphere. These conditions might even be taken as equivalent to those of Jones, where he passed the respective gases into permanganate solutions until the latter were discoloured. As in the previous experiments, the solutions became colourless after a few minutes' heating. The precipitates were allowed to remain on their filters unwashed for seven hours :—

No. of Experiment—	12	13	14	15	16	Neut Sol. 17
% $KMnO_4$ added of total required	0	25	50	75	87·5	50
% original MnO oxidised by atmosphere	11·8	5·1	3·3	1·8	1·3	0

If we bear in mind that the amount of atmospheric oxidation decreases in two ratios—one due to the decrease of MnO present, the other due to the covering-up property of the MnO_2—then the above numbers are just such as we would expect from mere mechanical mixtures of the two oxides MnO and MnO_2. There is no violent oxidation until 37·5 per cent. of the hydrate has been oxidised, and a sudden disappearance, or at least decrease, of the same after this stage has been reached, as we would be justified in expecting, were $Mn_2O_2(HO)_2$ a definite chemical compound, and a final stage of oxidation under these conditions. Experiment 17 was performed under these improved conditions in a neutral solution. The MnO_2 precipitated corresponded exactly to the $KMnO_4$ added, no oxidation having taken place. The filtrate was only slightly acid, owing to the liberation of sulphuric acid, thus : — $3MnSO_4 + K_2Mn_2O_8 + H_2O = 5MnO_2 + K_2SO_4 + 2H_2SO_4$. It gave a considerable precipitate of MnH_2O_2 with NaHO.

These experiments, therefore, not only refute the results obtained by Jones, but they demonstrate that the brown manganese precipitate, including that formed as a final product in the direct titration of organic bodies, contains the manganese in the state of the dioxide. This precipitate, in the case of direct titration, might either be produced from the action of the manganous salt formed in the solution upon the final $KMnO_4$ added; or it might be formed from the reduction of $KMnO_4$ to MnO_2 by the organic body itself. The probability existed that some organic bodies or their constituent radicals can reduce $KMnO_4$ to the form of MnO_2 *only*, even in acid solutions, as is the case with sodium thiosulphate in neutral and alkaline ones; and I was led back to work under similar conditions to those which Lunge and I § had recommended in the case of the latter salt—*i.e.*, of adding a large excess of $KMnO_4$, more than sufficient for reduction to MnO_2 only, then adding excess of standard $FeSO_4$ solution after the completion of the oxidation, and finally titrating back with $KMnO_4$ in the usual manner.

As is well known, potassium permanganate is constantly being employed in organic research as an oxidising agent, and numerous are the bodies which have been discovered by its aid. Impure products are, however, obtained, and in varying proportions, depending upon the amount of the reagent employed, temperature, and many other conditions. It has, therefore, only been generally employed as a qualitative reagent. It occurred to me, that by employing an excess of the reagent, and working under varying standard conditions, definite and simple compounds would be obtained, whose composition in each case might be determined qualitatively by ordinary analysis, and quantitatively by an estimation of the oxygen absorbed in the reaction. I hoped that by this means we might be enabled not only to possess

§ *Loc. cit.*

reliable processes for the valuation of commercial organic products, but that we might thereby be led to obtain a better insight into the nature of some of those complex organic principles, of whose constitution we are at present in almost absolute ignorance; as well as, perhaps, to increase our knowledge of the wonderful cycle of reducing and oxidising processes which attend the phenomena of life.

I was led to form these opinions from a study of the behaviour of solutions of various organic bodies in presence of a large excess of $KMnO_4$ under varying standard conditions. The determinations which I had in view were the following:—Oxygen yielded by excess of MnO_2 in acid, alkaline and neutral solutions respectively; oxygen yielded by excess of $KMnO_4$ in acid, alkaline and neutral solutions respectively. The latter would include the former: the difference would represent oxygen yielded by $KMnO_4$ in reduction to MnO_2 only, and would necessarily correspond to more stable bodies or radicals than those represented by the reduction of MnO_2. I further anticipated successive oxidations, more especially of a neutral one succeeded by an alkaline and acid one respectively, and an alkaline oxidation followed by one in acid solution. I found, however, that serious errors entered into my experiments, the elimination of which demanded the first attention.

I shall treat the subject in three divisions—namely, oxidation in acid, alkaline, and neutral solutions, respectively.

OXIDATION BY LARGE EXCESS OF $KMnO_4$ IN ACID SOLUTIONS.

Sulphuric acid is usually considered the only one generally applicable for titrations with permanganate, and as the objections to HCl and HNO_3 in working with excess of $KMnO_4$ and in hot solutions would be much more serious, H_2SO_4 quite free from these impurities was employed. The temperature at which oxidation proceeds is, as might be expected, an important factor—*i.e.*, as regards the speed, but not as regards the product of oxidation. Some bodies naturally require a higher temperature than others to obtain the final product of oxidation in a reasonable time; but I have reason to believe that all bodies—at least at ordinary temperatures—would reach that stage sooner or later. I think that valuable information might be derived from a study of the rate of oxidation of complex organic bodies under standard conditions, such as those I am about to describe, and at a temperature sufficiently low to allow of a number of accurate determinations of the progress of the oxidation at different stages. A graphic representation of the results obtained would indicate, by any abrupt change in the curve of oxidation, the completion of one, and the commencement of formation of another product of oxidation. Such manipulation, however, would be more especially interesting to the research chemist; for analytical purposes, a method by which the final product of oxidation is reached in a reasonable time is the only one which could be contemplated. The temperature of the hot-water bath was naturally that resorted to as being most convenient.

The permanganate solution which I employed, and which I shall designate as *normal*, was of such a strength that 1cc. was equivalent to 0·01grm. of pure metallic iron, or 0·00143grm. of oxygen. An organic, or other oxidisable solution, I also designate as *normal*, which requires the whole of the oxygen liberated by an *equal bulk* of normal $KMnO_4$, in its reduction to the state of MnO, for the complete oxidation of the body to CO_2 and H_2O.

To 50cc. of the normal solution of the organic body under investigation I added 100cc. normal $KMnO_4$ solution. It is important to observe that this quantity represents an excess of 20 per cent. $KMnO_4$, over the quantity necessary for complete oxidation, accompanied by a reduction of the $KMnO_4$ to MnO_2, only. 50cc. normal H_2SO_4 (1cc. = 0·049grm.) were then added. I generally made up the total bulk to the neck of a 750cc. flask with distilled water, and heated on the water-bath for a couple of hours, but now employ 250cc. flasks, when I find half-an-hour's heating sufficient. To avoid repetition, unless otherwise stated, it will be understood that the solutions employed were made up according to the *normal formula*—100cc. $n.KMnO_4$ + 50cc. *n*.organic solution + 50cc. nH_2SO_4 + 550cc. distilled water.

The results generally came out much too high, even for perfect oxidation, which indicated a loss of oxygen. The table below shows the representative numbers obtained.

These experiments show that the great loss of oxygen is not altered by varying the concentration of the solution, nor by decreasing the amount of free acid (21). They also indicate that the excessive loss is not due to the action of the acid upon the $KMnO_4$ alone (27), and also that it is not experienced by substituting ferrous sulphate for the organic body (26). I too hastily concluded from Experiment 26, that the loss was not due to the presence of MnO_2, and sought for the cause rather in some exciting action to the evolution of oxygen produced by the CO_2 generated in the case of organic bodies. I was, however, disappointed at the result of my endeavours to produce an equivalent effect in the experiment with ferrous sulphate, by introducing gradually into the solution—which had previously received a proportionate excess of sulphuric acid—35cc. of a 10 per cent. solution of potassium carbonate. The loss was even less than before—only 1·2 per cent. (28).

No. of Experiment—	18	19	20	21	22	23	24	25	26	27

In parallel experiments, with and without the addition of oxalic acid, and varying the times of heating, the results in Table A were obtained.

These experiments prove conclusively that in each case the loss increases with the length of heating, but is much more considerable in the solution which has been reduced by the organic body: although the actual permanganate in such a solution, where complete oxidation occurs, is only *one-sixth* of that to which no reducing agent has been added.

In experiments with glycerine and formic acid, confining the time of heating to half-an-hour, as seemed desirable from the above results, much more concordant indications were obtained—namely, 97 per cent. (35) and 103 per cent. (36) respectively. Encouraging as these results were, it seemed desirable to concentrate the attention upon the elimination of the error caused by the evolution of oxygen, as it would probably vary very much with the nature of the body under investigation.

No. of Experiment—	32	33	34
Reducing body added......	nil	Oxalic A.	nil
Time of heating...........	1 hour	3 hours	3 hours
Loss = cc. $nKMnO_4$	0·95	7·95	1·95

In recalling to mind the experiment in which ferrous sulphate was substituted for the organic body (26), it occurred to me that the excessive loss of oxygen might still be due to the presence of MnO_2, but that the ferric salt had the power to prevent, or diminish, the action. The next experiments confirm this view.

Manganous sulphate was formed by titrating 50cc. normal oxalic acid in the ordinary manner. 50cc. of normal $KMnO_4$ were added, the bulk made up to 750cc., and the solution heated on the water-bath three and a-half hours. The loss of oxygen was equal to 9·0cc. of the $KMnO_4$. Another experiment, in which the $MnSO_4$ formed above was substituted by an equivalent of crystallised $MnSO_4$, showed a loss equivalent to 9·5cc. of the normal permanganate. 50cc. $nFeSO_4$ solution, titrated and treated as above, gave a loss = 1·8cc. $KMnO_4$ only. A blank experiment with 100cc. $KMnO_4$, and no reducing body, indicated a loss of 2·4cc. The only difference in the experiment with the titrated $FeSO_4$ and those with $MnSO_4$ is that, in addition to $MnSO_4$, ferric sulphate is also present. To confirm the retarding action of the ferric salt still further, a solution of pure ferric sulphate was made with free H_2SO_4, the amount of which latter was of course allowed for in regulating the total acidity of the solution. I shall denominate such a solution *normal* which contains the same quantity of metallic iron in a given bulk, that a normal solution of ferrous sulphate does. The above solution was only 80 per cent. normal, but I shall always quote the quantity employed in terms of the normal solution. In an experiment with oxalic acid, under normal conditions, but with the addition of 40cc. normal ferric sulphate solution, a loss equivalent to 1·85cc. of normal permanganate was recorded. The foregoing experiments are compared in the following table :—

No. of Expt.—	37	38	39	40	41
Addition......	Titrated Oxalic A.	$MnSO_4$	Titrated $FeSO_4$	none	Oxalic A. + Fe_23SO_4
cc. $nKMnO_4$ lost..........	9·0	9·5	1·8	2·4	1·85

To find the action of the ferric salt upon MnO_2 alone, 50cc. normal $FeSO_4$ solution, exactly titrated, were added, in an experiment with oxalic acid under normal conditions. The $MnSO_4$ reduced the remaining $KMnO_4$, rendering the solution colourless in a few minutes. Absolutely no loss of oxygen was recorded in this experiment (42). This indicated that the small loss of oxygen experienced in the presence of the ferric salt was not due to the MnO_2 formed, and differed in this respect from the excessive loss in the absence of iron.

From the experiments in Table B we learn the influence of the ferric salt under varying conditions.

By normal $MnSO_4$ solution, I mean one which is able to reduce a solution of normal permanganate in equal measures. From the experiments I have already recorded, it will readily be seen that such a normal solution contains $\frac{3}{2}$-times the amount of actual Mn that an equal measure of normal $KMnO_4$ does. Experiments 44 and 45 confirm 42, demonstrating that no loss occurs, when all the $KMnO_4$ is wholly reduced to the form of MnO_2. The presence of the ferric salt, however, does not prevent the loss of oxygen from the $KMnO_4$, as such (43), in fact, it seems to increase the action considerably (48 and 49). From Experiments 46 and 47 we learn that the loss is less when a reducing body is present, this being no doubt due to the much smaller quantity of permanganate present (only ⅛th of the total) after reduction by the organic body. The action of the ferric salt is thus

seen to be of a two fold character; it acts as an accelerator in the presence of much $KMnO_4$ and little MnO_2 (49), but a retarder in the presence of much MnO_2 and little $KMnO_4$ (51). The loss which we wish particularly to avoid is that which occurs after the oxidation of the organic body is complete—*i.e.*, when a considerable quantity of MnO_2 has been formed, and only a small excess of $KMnO_4$ remains: hence the beneficial action of the ferric salt.

Under these improved conditions various organic bodies were subjected to oxidation, with much more satisfactory results, as indicated below. The time of heating was 2½ hours in each case, and 20cc. normal $Fe_2\,3SO_4$ were added, other conditions being normal:—

No. of Exp.—	52	53	54	55
Body added	Formic A.	Glycerine.	Tannin.	Cane Sugar.
% indicated..	106·2	99	93·2	85·8

With a total bulk of 200cc., the solution being heated for half-an-hour only, the numbers given in Table C (page 103) were obtained.

A parallel experiment with cane sugar, in which the 100cc. $KMnO_4$ were added in five equal portions at equal intervals, thereby avoiding excess of $KMnO_4$, indicated only 80 per cent. (63). Probably the difference in the two experiments was due to loss of oxygen, from the action of the acid on the free $KMnO_4$. The alcohol was most distinctly oxidised to acetic acid, as evinced by the smell. The percentage indicated also agrees closely with the formation of that body. Acetic acid itself is unoxidised (62), the small amount (0·5 per cent.) of oxidation recorded, after deducting the calculated loss, being probably due to impurity in the acid.

Such results as these recorded, although bearing the impress of approximations to certain absolute quantities I was endeavouring to estimate, were not so perfect as those to which I had aspired. The errors due to loss of oxygen have not been allowed for in the above experiments, except in the case of acetic acid; indeed, it would be difficult to do so. Although we know the quantity of free $KMnO_4$ existing both before and after reduction, we do not know when the oxidation is completed; and even did we know this, we could not be certain whether any oxygen at all would be lost until, the completion of the oxidation. Simultaneous experiments, without addition of any reducing body, and with 100 and 20cc. $nKMnO_4$, indicated a loss of oxygen equivalent to 4·8 per cent. (63) and 0·9 per cent. (64) respectively, in terms quoted above. Now, if we assume that no loss occurs until the body reaches its final stage of oxidation; and, further, that this latter occurs after ¼ hour's heating, both assumptions being within the region of probability; then the loss could scarcely have exceeded 0·5 per cent., except in the case of alcohol, where the oxidation is so incomplete.

Another possible source of error was impurity in the bodies under investigation. Although they were obtained in the usual course as pure chemicals (excepting the loaf sugar, which was of ordinary commercial quality), their absolute purity was doubtful in some cases. Beyond drying in the hot water oven, or estimating the acidity or specific gravity, they were not subjected to any systematic analysis. Through the kindness of Messrs. Mawson & Swan, I have been supplied with some specially pure chemicals, which will assist in the elimination of this source of error. Before making use of them, however, I was anxious to still further improve the process if possible; and, accordingly, more systematic experiments were instituted, which I shall now record. At this stage I determined, in order to utilise the time as much as possible, to reduce the total bulk of solution to 250cc., and the time of heating to half-an-hour, except in cases where a longer period was necessary, to ensure greater accuracy in the estimation of small differences in the errors derived from working under varying conditions under comparison.

Throughout this investigation, I have been frequently impressed with the excessive caution which must be exercised in drawing conclusions from experiments, however carefully made. We have seen that there is a slight action of sulphuric acid upon potassium permanganate in the absence of iron salts, causing a small loss of oxygen. When $MnSO_4$, or an organic body which is capable of reducing the $KMnO_4$ *incompletely* to the form of MnO_2, is added, we find a very great increase in the amount of oxygen evolved, although the loss due to the action of the acid on the $KMnO_4$ as such, must necessarily be considerably decreased. It seemed very natural to conclude that the increase was due to the action of the H_2SO_4 upon the MnO_2 as such. In the experiments already recorded I was labouring under this impression. As the experiments were strictly comparative in each case, their value was not diminished by the subsequent revelation that this hypothesis was a false one. As a matter of fact, I found that the loss of oxygen due to the action of the acid upon MnO_2 is absolutely nil under the conditions which prevailed. With a view to determine the amount of loss due to the action considered, to 50cc. $nC_2H_2O_4$ just sufficient $KMnO_4$ was added to reduce all the manganese to the form of MnO_2, 50cc. nH_2SO_4 were then added, *but no iron salt*. The bulk was made up to 250cc., and the solution heated one hour. The solution was only very faintly coloured after heating. A loss of *only* 1·35cc. $KMnO_4$ (65) was shown. Surprising as this result was, I was still more astonished at the result of a corresponding experiment, in which the heating was prolonged to 4½ hours. No more oxygen was evolved than in the preceding case—*i.e.*, only the equivalent of 1·5cc. $nKMnO_4$ (66). As a repetition of the old experiments, with the proportions of 100 $KMnO_4$ to 50cc. oxalic acid, proved that the laws of nature had in no degree been enjoying a temporary relaxation, the only conclusion which could be formed was, that the presence of *both* $KMnO_4$ and MnO_2 is required for the excessive evolution of oxygen, which had been so frequently observed. Final test experiments completely confirmed this conclusion. To 50cc. $nC_2H_2O_4$, already titrated, only one-half the quantity of $KMnO_4$ was added necessary to oxidise the Mn to MnO_2. Absolutely no loss of oxygen was recorded after half-an-hour's heating (67). A parallel experiment, with the usual proportions of $KMnO_4$ and oxalic acid, indicated a loss of 4·4cc. $nKMnO_4$ (68). This result was most important, and suggested a method of analysis to which I shall refer later on. It also furnishes the proof that in the experiments (Nos. 1 and 6) in which the $KMnO_4$ and $MnSO_4$ were added in the theoretical quantities to convert the whole of the manganese into MnO_2, similar to the conditions of 62 and 63, the quantity of oxygen lost is not sufficient to be taken into consideration, more especially in No. 6, which received only half-an-hour's heating. Jones* makes a great point of the liberation of oxygen in oxidations by permanganate. He states that it occurs under all the conditions it is possible to imagine, and he attributes the cause of its generation to the tendency to the formation of Mn_2O_3,

---

* *Loc. cit.*

which he considers to be the stable oxide of manganese, and the final product of oxidation by $KMnO_4$ in all cases. MnO_2 he finds to act in the same manner as $KMnO_4$, and would lead one to question the accuracy of Fresenius and Will's method for the valuation of that ore, on account of the oxygen evolved in the reaction. Now, my experiments throw light upon many of the results obtained by Jones with regard to the evolution of oxygen, but they show at the same time that the above-mentioned method is free from reproach in this respect. They further show that MnO_2 is really the stable compound of manganese in acid as well as other solutions; and, indeed, this very fact accounts for the liberation of oxygen from $KMnO_4$, the evolution of that gas not being completed until the whole of the Mn has been reduced to the state of MnO_2, as is still more strikingly illustrated by the following experiments, with varying amounts of permanganate solution. Total bulk = 250cc.; free acid = 50cc. nH_2SO_4; organic body = 50cc. $nC_2H_2O_4$:—

No. of Experiment—	69	70	71
cc. Free $KMnO_4$ after reduction by oxalic acid ..	15·65	32·3	82·3
Time of heating	½hr.	½hr.	½hr.
cc. $nKMnO_4$ lost	4·1	6·15	10·55

No. of Experiment—	72	73	74
cc. Free $KMnO_4$ after reduction by oxalic acid ..	15·65	49	99
Time of heating	3hrs.	3hrs.	3hrs.
cc. $nKMnO_4$ lost	9·4	25·65	46·5

Of course no iron salt was present in these experiments. It is very interesting to observe that the loss increases very nearly in the ratio of the square root of the amount of $KMnO_4$ present, in the first three experiments with the shorter heating, from which we can form an idea of the speed of reduction. In the last three, the reduction of the $KMnO_4$ was more or less complete, as represented by the following equation:— $K_2Mn_2O_8,nMnO_2 + H_2SO_4 = n + 2MnO_2 + K_2SO_4 + H_2O + O_3$. This shows that to effect complete reduction of $KMnO_4$ to MnO_2 under the influence of pre-existing MnO_2, a loss of oxygen occurs = $\frac{3}{5}$ of the total oxygen available from the $KMnO_4$. Keeping this in view, we learn that the reduction in Experiment 72 was theoretically complete, and this was borne out by the solution being almost colourless at the termination of the heating. In Experiments 73 and 74, 87·2 and 78·3 per cent. respectively of the reduction represented by the above equation had been completed.

Comparative experiments, with no reducing body present, gave the following results :—

No. of Experiment—	75	76	77	78
cc. $nKMnO_4$ added	25	100	25	100
Time of heating	½hr.	½hr.	2hrs.	2hrs.
cc. $nKMnO_4$ lost	0·2	0·5	0·4	1·05

Here we can form no very reliable conclusion with regard to the speed of reduction of the $KMnO_4$, although it seems to increase in the ratio of the square root of the quantity of $KMnO_4$ present as we found before. Not only is the loss too small to found any weighty conclusions upon it, but if I am right in my opinions we should have no reduction at all if no impurity were present in the $KMnO_4$, and no trace of a reducing agent were otherwise introduced. But if we presume the presence of a reducing agent in the solution, should it even be an impurity of a manganous salt in the $KMnO_4$, equivalent to 0·1 per cent. in the above experiments, then it is easily seen we have the conditions existing for the initiation of the reaction expressed by the equation given above. Corresponding experiments were instituted in presence of ferric sulphate. 20cc. nFe_23SO_4 were added to the usual proportions. With 50cc. n oxalic acid added, the following results were obtained :—

No. of Experiment—	79	80	81	82	83
Time of heating	½hr.	½hr.	½hr.	2hrs.	2hrs.
cc. Free $KMnO_4$ present after reduction	25	50	75	25	75
cc. $nKMnO_4$ lost	0·8	1·0	1·3	3·45	8·95

From these experiments we learn that the loss of oxygen is only about 15 per cent. what it is without the addition of the ferric salt, and it increases more in proportion to the free $KMnO_4$ present than in the ratio of the square root of that quantity; at least in the case of the longer heating, which gives naturally more accurate results.

With the iron salt, but in absence of any reducing body, the following results were obtained :—

No. of Experiment—	84	85	86	87	88
cc. $nKMnO_4$ added ..	25	50	75	25	75
Length of heating	½hr.	½hr.	½hr.	2hrs.	2hrs.
Oxygen = cc. $nKMnO_4$ lost..................	0·15	0·6	1·6	1·9	8·2

The ferric salt, as we had previously seen, increases the loss considerably when no MnO_2 is present, and the loss in this case increases in a *greater ratio* than the amount of $KMnO_4$ present: in fact, in the experiments above, with half-an-hour's heating, it closely corresponds to the *square* of the amount of permanganate.

The influence of the ferric salt is quite a paradox, being in one case an accelerator and in another a retarder of the action of the acid on the $KMnO_4$. Without iron, the loss increases with the increase of MnO_2, while under its influence the loss increases with the amount of $KMnO_4$, and decreases with the increase of MnO_2. Hence two problems are presented for solution—viz., the cause of the retarding action with excess of MnO_2, and the cause of the accelerating action with excess of $KMnO_4$. The most likely explanation I can offer is that the iron salt is really an accelerator, but that it has the power of neutralising the action of the MnO_2 after a certain excess has been formed, and this opinion has been borne out by subsequent experiments. The Fe_23SO_4 does not, however, perfectly neutralise the action of the MnO_2, for by comparing the above experiments (79 with 84, etc.) we find that for the same quantity of free $KMnO_4$ a greater loss is experienced in the presence of MnO_2, at least up to a certain point.

In order to find if iron were precipitated with the MnO_2, $KMnO_4$ was completely reduced by $MnSO_4$ solution in presence of ferric sulphate, the solution was filtered, and the precipitate was well washed and dissolved in oxalic acid. To one portion ammonium hydrate was added in excess when a considerable precipitate of $Fe_2H_6O_6$ was formed. The other portion was acidified with HCl, and $BaCl_2$ added, but no precipitate occurred. We learn then that iron is precipitated with the MnO_2, and in the form of oxide, not as sulphate.

It seemed important to ascertain if other salts had the same power of neutralising the MnO_2. The following were tried, added in proportion equivalent to 25cc. $n Fe_2 3SO_4$ The $KMnO_4$ added was increased to 108·3cc., leaving 25cc. free $KMnO_4$ after reduction by the 50cc. n.oxalic acid, added in each case. The heating lasted two hours.

No. of Experiment—	89	90	91	92	93
Salt added	none	$Fe_2 3SO_4$	$MgSO_4$	$ZnSO_4$	$Al_2 3SO_4$
cc. $n KMnO_4$ lost	13·0	2·55	12·3	11·9	9·25

No. of Experiment—	94	95	96	97
Salt added	$Cr_2 3SO_4$	$K_2Cr_2O_7$	$NiSO_4$	$CoSO_4$
cc. $n KMnO_4$ lost	0	8·3	9·1	5·55

The peculiar action of the chromic sulphate is easily explained. The chromium is itself oxidised to the state of the trioxide by $KMnO_4$, under the conditions of experiment. The solution was rendered colourless, showing that the $KMnO_4$ had been completely reduced; and, as we have already learned, under such conditions no loss of oxygen is experienced. In titrating back the solution to which $K_2Cr_2O_7$ had been added, allowance was of course made for the $FeSO_4$ it was capable of oxidising. As an indirect result of experiment No. 94, we find that $KMnO_4$ is a much more active oxidising agent than chromic acid in solution. This was confirmed by experiments in which an equivalent amount of $K_2Cr_2O_7$ was used instead of $KMnO_4$. The results are strictly comparable with Experiments 52 to 55, but no ferric salt was added. The loss of oxygen from $H_2Cr_2O_7$ is nil (102).

No. of Exp.—	98	99	100	101	102
Body added ..	Formic A.	Glycerin	Tannin	Cane Sugar	None
% oxidised	7·0	14·0	51·8	12·1	0
% with $KMnO_4$	106·2	99	93·2	85·8	—

Returning to the experiments with various salts, we see that Mg and Zn are without influence, while the others are all inferior to iron. An additional objection to Cr, Co, and Ni, lies in the insensitiveness of the end reaction, on account of the colour imparted by the salts themselves to the solution. Cobalt sulphate, which proved the next best to iron, was tried in double quantity, with no better result, 5·3cc. $KMnO_4$ being lost (Experiment 103). In conjunction with iron, it proved also of no advantage. With equal quantities of the two salts, a loss of 3·05cc. was recorded (104).

It was next necessary to determine the best amount of ferric sulphate to add to the solution. I had reduced the amount in the foregoing experiments to 20cc. normal, on account of the action on the $KMnO_4$; more especially as I had found this amount to be nearly as efficient as 40cc., as first used to check the action of the MnO_2. More accurate experiments proved that an advantage existed in increasing this amount considerably. The general average of these results is given below. To 50cc. n.oxalic acid, sufficient $KMnO_4$ was added to leave 25cc. free permanganate after reduction to MnO_2. The free acid present was always equal to 50cc. $n H_2SO_4$, in addition to that of the acid itself. The heating was prolonged for two hours.

No. of Experiment—	105	106	107	108	109	110	111	112
cc. $n Fe_2 3SO_4$ added	8	12	16	20	24	28	32	36
cc. $n KMnO_4$ lost	5·1	4·2	3·95	3·65	3·1	3·1	3·1	2·85

No. of Experiment—	113	114	115	116	117	118	119
cc. $n Fe_2 3SO_4$	40	48	60	80	100	120	160
cc. $n KMnO_4$ lost ..	2·6	2·55	2·3	1·5	1·2	1·2	1·1

We gather from these experiments, that there is a continual decrease in the loss until about 100cc. $Fe_2 3SO_4$ are added, but no advantage in the further addition of the salt. A confirmation, and, at the same time, an explanation, of this result was obtained from an analysis of the precipitates formed by the addition of 50cc. $n C_2H_2O_4$, or its equivalent, in the presence of 25, 50, 81 and 130cc. respectively of normal $Fe_2 3SO_4$. In order to avoid the trouble of separating the Mn and Fe in the precipitates, the iron was estimated in the filtrate directly, and the amount in the precipitate determined by difference. To reduce the amount of manganese in the solution to a minimum, only sufficient $KMnO_4$ was added to oxidise the body, and the manganous salt formed, completely to MnO_2 as already explained. After heating, the small quantity of $KMnO_4$ still remaining was reduced with $FeSO_4$, whose amount was carefully noted. The iron was always determined gravimetrically.

No. of Experiment—	120	121	122	123
cc. $n Fe_2 3SO_4$ present	25	50	81·3	130·1
cc. $n FeSO_4$ required to decolourise	0·5	1·1	0·15	0·25
Equiv. cc. $n Fe_2 3SO_4$ in ppt. ..	3·55	6·6	10·05	12·9
% Fe in ppt. on total present..	13·9	12·9	12·3	9·9

From the above, we learn that the quantity of iron precipitated bears a certain ratio to the total iron, until a particular stage is reached (between the addition of 81·3 and 130·1cc. $Fe_2 3SO_4$), when it appears that little further precipitation occurs. Now, if we estimate the amount of $Fe_2 3SO_4$, which would be required to give a precipitate equivalent to, say, 12·5cc. $Fe_2 3SO_4$, as 12 per cent. of the total, we find 104cc. would be required. This, as we have seen, is about the stage after which no material advantage is derived from the further addition of the ferric salt. But the ratio of the Fe_2O_3 derived from 12·5cc. $n Fe_2 3SO_4$, to the MnO_2 derived from 83·3cc. $n KMnO_4$, is exactly expressed by the formula, $3Fe_2O_3.8MnO_2$. It seems, therefore, to be a warantable conclusion, that the advantage gained by the addition of the ferric salt, is due to the formation of this compound, or its hydrate.

The following results were obtained from experiments with varying quantities of $Fe_2 3SO_4$, but in absence of a reducing body, 40cc. $n KMnO_4$ were added, and the heating lasted two hours:—

No. of Experiment—	124	125	126	127	128
cc. $n Fe_2 3SO_4$ added ..	0	20	40	80	100
Loss = cc. $n KMnO_4$ ..	1·0	4·6	6·0	6·5	6·8

We observe that the loss rapidly increases until between the addition of 20 to 40cc. $Fe_2 3SO_4$, beyond which the increase is very small. Now we know the great similarity which exists between the elements, manganese and iron, and their oxides. Is it not possible, then, that an unstable oxide of iron exists corresponding to the dioxide of manganese; that this compound is formed by the reduction of the $KMnO_4$; and that it is immediately split up again into Fe_2O_3 and O by the action of the acid? This seems to me a very plausible explanation of the accelerating action of the iron salt, and it receives some support from the fact, that the maximum acceleration occurs when the $KMnO_4$ and $Fe_2 3SO_4$ are present in the proportions necessary to satisfy the following equation—
$K_2Mn_2O_8 + 3Fe_2 3SO_4 + 8H_2O = K_2SO_4 + 8H_2SO_4 + 2MnO_2 + 6FeO_2$.

We have already been impressed with the magnitude of the loss experienced from the action of $Fe_2 3SO_4$ in the presence of much $KMnO_4$. The following experiments with 100cc. $nKMnO_4$, and heated for three hours, show this still more strongly:

No. of Experiment—	129	130	131
cc. $Fe_2 3SO_4$ added	0	20	20
Loss = cc. $nKMnO_4$	2·3	18·6	15·6

In Exp. 131, 18 per cent. of the $KMnO_4$ had been previously reduced by the addition of $MnSO_4$.

The following experiments are instructive as showing the amount of oxygen lost, with varying proportions of MnO_2 and $KMnO_4$ present, both with and without the iron salt. The MnO_2 present was regulated by the amount of oxalic acid added:—

WITHOUT IRON SULPHATE. HEATED 2¼ HOURS.

In summing up the evidence derived from the foregoing experiments, I came to the conclusion that the beneficial action of the ferric salt could be considerably enhanced, if it could be rendered so difficultly soluble as to be at once precipitated by the MnO_2 formed; thereby rendering the theoretical quantity necessary to form $3Fe_2O_3 8MnO_2$ sufficient to be added, instead of eight times that quantity, which we had found otherwise to be necessary. Of the salts whose services could be enlisted, I concluded that ferric phosphate would be the most likely to succeed, and in this choice I was most fortunate. In two parallel experiments with 50cc. $nC_2H_2O_4$, and under the usual conditions, I obtained quite as good a result with 20cc. $nFe_2 3SO_4$, to which I had added 2grms. of crystallised sodium phosphate, as with 160cc. $Fe_2 3SO_4$ alone, with which I had previously obtained the best result. The losses were 1·0cc. $nKMnO_4$ with (147), and 1cc. without, the addition of phosphate (148). The heating lasted two hours. In repeating these experiments, they were most satisfactorily confirmed, with the same time of heating, as follows:—

No. of Experiment—	149	150	151	152	153	154
cc. $nFe_2 3SO_4$ added ..	100	0	8	16	100	3grm. $CaSO_4$
Grms. cryst. Na_2HPO_4 added	0	2	2	2	2	—
Loss = cc. $nKMnO_4$	1·3	1·3	0·7	0·7	1·5	8·0

Although we find here a considerable advantage in the presence of the phosphate alone (150), it is the combination of the phosphate and the iron which is the most beneficial. We learn also that there is an actual disadvantage in adding a large quantity of ferric sulphate with the phosphate (153), which indeed we might have expected. The experiment with calcium sulphate was made with a view to find if the mere presence of a precipitate would have any beneficial result. Such a view is not confirmed.

The following series shows that between 4 and 12cc. is the best amount of ferric sulphate to be added. 140cc. $nKMnO_4$ were employed in order to leave a large excess of free permanganate after reduction by the 50cc. $nC_2H_2O_4$, that the differences might be the more accurately estimated. The heating lasted 1½ hours:—

No. of Experiment—	155	156	157	158	159	160	161	162
cc. $nFe_2 3SO_4$ added..	0	0	2	4	8	12	16	20
Grms. Na_2HPO_4 do.	0	2	2	2	2	2	2	2
Loss = cc. $nKMnO_4$ ..	25	8	2·2	1·6	1·4	1·6	1·9	2·0

Here again the great advantage of the phosphate alone should be noted, as also the great influence of such a small quantity of the sulphate as is represented by 2cc.—*i.e.*, 0·07grm. $Fe_2 3SO_4$, sufficient only to yield a precipitate with the MnO_2, represented by the formula $Fe_2O_3.16MnO_2$.

A corresponding series, to find the best amount of phosphate, yielded the following results. 140cc. $nKMnO_4$ and 8cc. $nFe_2 3SO_4$ were employed, and the heating lasted 1½ hours:—

No. of Experiment—	163	164	165	166
Grms. crystallised Na_2HPO_4 added	¼	¾	2	3
Loss = cc. $nKMnO_4$	2·0	1·1	1·2	1·0

No. of Experiment—	167	168	169	170
Grms. crystallised Na_2HPO_4 added	5	5	10	10 (no Fe)
Loss = cc. $nKMnO_4$	0·7	0·8	0·8	2·1

5grms. are seen to be sufficient to add under the conditions existing. The increased phosphate has a marked benefit even in absence of iron (170), although it is evident that the iron salt cannot be dispensed with.

The influence of various amounts of acid is shown by the following series. 5grms. phosphate, and 10cc. iron solution were employed, other conditions being as before:

No. of Experiment—	171	172	173	174
cc. total Normal Free Acid ..	25·0	50·0	100·0	200·0
Loss = cc. nKMnO$_4$	0·8	0·7	1·3	5·0

No advantage is derived, therefore, from decreasing the amount of acid; but probably there would be an advantage gained in point of speed of oxidation by increasing it to, say, 75cc., which would more than compensate for the increased loss with the same time of heating, more especially as the large quantity of phosphoric acid liberated might not be so energetic in inducing the decomposition of the organic bodies whose investigation was contemplated as sulphuric acid.

The following series, under the improved conditions to which we have attained, shows most strikingly the advantage of the addition of phosphate. 140cc. n KMnO$_4$ were employed, and the heating lasted two hours:—

No. of Experiment—	175	176	177	178
cc. nFree Acid present	50·0	50·0	75·0	50·0
cc. nFe$_2$3SO$_4$ added	8·0	4·0	6·5	80·0
Grms. Na$_2$HPO$_4$ added	5·0	5·0	4·0	0·0
Loss = cc. nKMnO$_4$	1·0	1·1	1·2	5·3

We note, also, that with 4grms. Na$_2$HPO$_4$ and 75cc. acid, we get nearly as good a result as with 5 and 50 respectively.

The influence of the phosphate in presence of varying proportions of MnO$_2$ and free KMnO$_4$., obtained from a total of 100cc. added, is here exhibited. The time of heating was two hours:—

No. of Experiment—	179	180	181	182	183	184	185	186	187	188	189
cc. nAcid present	50	50	50	75	75	75	75	75	75	75	75
cc. nC$_2$H$_2$O$_4$ added	25	50	75	0	25	50	75	0	25	50	75
cc. free KMnO$_4$ left	58·3	16·6	0	100	58·3	16·6	0	100	58·3	16·6	0
cc. nFe$_2$3SO$_4$ added	8	8	8	6·5	6·5	6·5	6·5	6·5	6·5	6·5	6·5
Grms. Na$_2$HPO$_4$ added	5	5	5	4	4	4	4	2	2	2	2
cc. nKMnO$_4$ lost	1·1	0·7	0·4	1·2	0·9	0·4	0·2	7·0	2·3	0·7	0·2

The special function of the phosphate, when added in large quantity, is, as we here see, in checking the accelerating action of the ferric salt in presence of much KMnO$_4$, which had caused so much anxiety before. When 4 or 5grms. of phosphate are added, we see it is reduced to a minimum. I have ascertained that the iron is almost completely precipitated under such conditions. 50cc. n oxalic acid were exactly titrated with KMnO$_4$. 16·25cc. nFe$_2$3SO$_4$, and 5grms. crystallised Na$_2$HPO$_4$ were added together with two-thirds extra KMnO$_4$ of the quantity required for titration. After heating, 0·8cc. nFeSO$_4$, were required to decolourise the solution. Ferric phosphate was found in the filtrate equivalent to only 2cc. nFe$_2$3SO$_4$; or, if we deduct the ferrous sulphate introduced, only 1·2cc.—*i.e.*, only 7·4 per cent. of the iron salt added remained in solution, the remainder having been precipitated. Although we found the error due to the accelerating effect of the ferric sulphate to be much less serious in actual work than the error which resulted in its absence, still, in the case of bodies which are not oxidised at all, or only partially, or even wholly but very slowly, this error might be very considerable. Now, however, we are rendered, in a sense, independent of the different behaviours of the organic bodies under investigation. Here we have a regular scale of errors, of only small dimensions, which we can allow for, after obtaining the indicated oxygen absorbed. In the *very worst* case, that of a body unoxidisable, as in Experiment 182, we see that the error in the case of half-an-hour's heating represents an oxidation of 0·6 per cent. of the body under investigation. But as this error can be accurately allowed for, the errors which may creep in are only such as might be attributed to manipulation.

In order to make quite certain that the phosphate introduced does not interfere in any way with the oxidation, three of the organic solutions already employed were subjected to oxidation with addition of 6·5cc. nFe$_2$3SO$_4$, and 4grms. Na$_2$HPO$_4$; 75cc. n free acid being present. The heating lasted for thirty minutes. The following are the results:—

No. of Experiment—	190	191	192
Body oxidised	Glycerin	Alcohol	Cane Sugar
Per cent. indicated after deducting for loss..................	97·6	32·2	82·2

These numbers agree within a per cent. with the numbers we already obtained with Fe$_2$3SO$_4$ (Experiments 56, etc.); except in the case of alcohol, where the oxidation is only one-third of that possible, and we know that the iron alone in this case gives too high a result, on account of the large quantity of free KMnO$_4$ remaining after oxidation has been effected. In such a case, where great accuracy is required, it is preferable to employ a larger quantity of the body, such as would absorb about the same quantity of oxygen as is yielded by 50cc. nKMnO$_4$ when completely reduced. With this view it is expedient to concentrate the solutions as much as possible. Instead of 100 nKMnO$_4$, I now add 50cc. double normal solution; and the phosphate, iron, and free acid I make up in one solution, of which only 20cc. are required. This allows for the introduction of 175cc. of the organic solution, should such an amount be necessary. Bodies which are generally considered insoluble, or nearly so, may frequently be rendered available by this means. If this bulk were too small, they might still be made up to say 750cc., and a longer heating given. Indeed, potable waters would require to be treated in this way, unless evaporation were resorted to. It is quite probable that certain insoluble bodies may be oxidised, if means be taken to allow of their free circulation in the solution.

With regard to the height of the oxidation, this is indicated by the change of colour the solution undergoes, owing to the precipitation of MnO_2. In the above experiments, it occurred after from five to ten minutes with glycerine and alcohol; in the case of sugar not until fifteen or twenty minutes. The progress of the oxidation can also be observed from the transparency of the solution, as seen through the neck of the flask: and might be roughly estimated by a comparison with similar flasks containing known amounts of $KMnO_4$. If any doubt existed as to the oxidation being complete, it would be advisable to repeat the experiment, giving one or two hours' heating, and deducting the small error which occurs.

Probably in no analytical work is greater care and more scrupulous cleanliness required than with such experiments as those described. Traces of bodies which are otherwise innocuous or even beneficial may be productive of the greatest harm. Precautions must be taken against the introduction of dust or organic matter from the air, into the flasks or solutions employed. The use of antiseptics must be particularly avoided. Before using any flask for this description of work, it must be first thoroughly "sterilised" by boiling in it an acidified solution of $KMnO_4$. I have known $KMnO_4$ to be reduced in a flask which had contained alcohol, although it had, previous to employment in a blank experiment, been well washed and rinsed with distilled water. It is of course much preferable to keep certain vessels and measures exclusively for this work. All the chemicals employed must also be tested in blank experiments, and any oxidisable impurity they may contain allowed for.

I have decided to employ 8cc. $n Fe_2 3SO_4$ to 4grms. Na_2HPO_4, with free acid equivalent to 75cc. normal. This corresponds very closely to the formula $Fe_2 3SO_4 . 15Na_2HPO_4 . 50H_2SO_4$ to every four molecules of MnO_2 precipitated. My solution is made up as follows:—15grms. of pure ferric sulphate (calculated anhydrous) are dissolved in about 300cc. of distilled water acidified with about 50cc. of pure sulphuric acid (sp. gr. = 1·84). In another beaker 200grms. of pure crystallised sodium phosphate are dissolved in 300 or 400cc. of distilled water acidified with the remainder of 100cc. of the sulphuric acid. When solution is complete the liquids are mixed, the bulk made up to one litre, and the solution filtered. 20cc. of this solution are added to 50cc. (2n)$KMnO_4$, in a flask containing 250cc. when filled to the neck. 50cc. of the normal organic solution are added, and the bulk made up to 250cc. The solution is heated for thirty-five minutes on the water-bath, which allows five minutes for the temperature to rise. In dissolving the precipitate after oxidation, it is well to have the ferrous sulphate solution strongly acid, in order that no phosphate may remain undissolved. I employ a normal solution of ferrous sulphate containing free acid equivalent to a double normal solution. This is made by dissolving 50grms. crystallised $FeSO_4$ in water acidified with 108cc. sulphuric acid (sp. gr. = 1·84), and making up the bulk to one litre. The strength of this solution must be tested daily when in use. The flask must be carefully rinsed with the ferrous sulphate solution run in from a pipette, to dissolve any adhering MnO_2; this is very easily effected. After the solution is thoroughly clear, I make up the bulk to about 800cc. in a beaker with cold distilled water, when it will be found sufficiently cool to titrate at once. It is possible to complete six experiments in the course of an hour by this method of working.

In order to estimate quite accurately the error introduced by the loss of oxygen in employing the solution I have described, experiments were made without addition of a reducing body, and with 50cc. n.oxalic acid added, the heating being extended to *five hours*. Parallel experiments were also made with the iron increased to 12·5cc. normal, but, as will be seen, the results are almost identical:—

No. of Experiment—	193	194	195	196
cc. $n Fe_2 3SO_4$ present	8	8	12½	12½
Reducing body added	none.	Oxalic acid.	none.	Oxalic acid.
Loss = cc. $n KMnO_4$	2·8	0·6	2·8	0·5
Error = per cent. of body per half-hour	0·56	0·12	0·56	0·10

We see here that the error introduced is very constant compared with former results. For a body which is found to be wholly or nearly completely oxidised, if we make a deduction of 0·15 or 0·2 per cent. we may be sure that the result obtained is within 0·1 per cent. of the truth, at least as far as the error introduced by the loss of oxygen is concerned.

Acetic acid, as we have seen, is not oxidised by the permanganate. In order to determine if this was absolutely the case, and whether it could be substituted for sulphuric acid in case of necessity, the following experiments were tried:—A neutral solution of sodium acetate, containing 8grms. of the crystallised salt (*i.e.*, more than sufficient to combine all the free H_2SO_4), was introduced in place of the organic body in both experiments.

No. of Experiment—	197	198
Length of heating	½hr	2hrs.
Loss = cc. $n KMnO_4$ after deducting for error	2·1	3·4

From the loss in 197 we can draw no conclusion, as it includes any impurity in the acetate: but from the difference in the two experiments (= 1·3) we obtain the loss due to oxidation of the acetic acid itself in 1½hrs. We learn, then, that there is a slight oxidation of the acetic acid when present in very large quantity, which would not exclude its use, however, where sulphuric acid could not be employed. An additional error would be introduced which would not be greater than 0·8 per cent. (*i.e.*, in the worst case, where no oxidation occurs), provided the acid were perfectly pure.

The accompanying diagram illustrates the most important results obtained from this investigation, and will serve the purpose of a summary of the same. It is sufficiently clear to render detailed explanation unnecessary. The curves are drawn from an independent series of experiments. The height of any point in the curve indicates the speed of the reduction of $KMnO_4$, after the percentage indicated on the base line has been reduced. The points were found by adding varying quantities of normal oxalic acid, heating for a convenient time, and estimating the oxygen lost during the interval. The speed of reduction calculated therefrom was ascribed to the middle point between the reduction artificially initiated, and that finally indicated after heating. The diagram is drawn to a scale of millimetres, from which the percentage of the complete reduction, or

the indicated percentage error per given time corresponding to any given initial reduction of the $KMnO_4$, or *vice versâ*, may be accurately measured. It should be noted that the maximum speed of reduction with no addition, and the minimum speed of reduction with $Fe_2 3SO_4$ added, very nearly correspond to an initial reduction of 60 per cent. With the smaller amount of $Fe_2 3SO_4$, the indication is similar, showing that these maxima and minima depend on the ratio of MnO_2 to $KMnO_4$. The enormous initial speed of reduction with $Fe_2 3SO_4$, as well as the nearly complete annihilation of the reduction with Na_2HPO_4, should be noted.

Practical Applications.

The chief recommendation of such a method as I have described to a Society like ours lies in the advantages which it offers for the rapid and accurate estimation of commercial organic products, and these occupy a position of the highest importance in English chemical industry. For the determination of the organic matter in potable waters, and in the waste liquors of the numerous manufactories which largely employ organic materials, the method will doubtless prove of the greatest practical importance.* For the estimation of alcoholic, and possibly ethereal, solutions when largely diluted, it presents a more rapid solution than the specific gravity method. For the examination of milk and other animal secretions its application will be obvious.

But to the research chemist the field laid open is much wider. The want of a method for estimating the oxygen in organic bodies directly, has long been felt. Now, although this method does not supply that want in every case, probably in the vast majority of organic bodies it does so, and will at least prove a valuable aid to ordinary elementary analysis. The probability is that the number of organic bodies which the permanganate will not oxidise, under the conditions obtaining, is very small; very possibly acetic acid is the only body. Sugar we found to be oxidised to the extent of 82·2 per cent. This corresponds to the absorption of 20 atoms of oxygen per molecule. Now, if one molecule of acetic acid were a product of the oxidation, we can account for the additional four atoms of oxygen required for complete oxidation not being absorbed.

The time is immature to speak definitely in the matter, but I foresee the application of this method possibly for the ultimate analysis of organic bodies; in which case carbon, oxygen, and nitrogen would be determined directly in one experiment, and the hydrogen by difference. In the case of nitrogenous bodies, I have reason to believe the nitrogen is evolved as gas. Both it and CO_2 might be collected over mercury and measured, and the nitrogen subsequently measured after absorption of the CO_2 by potash.

I hope to treat of the oxidation of organic bodies by means of MnO_2 in acid solutions, as well as of oxidations by permanganate in neutral and alkaline solutions, and of analytical methods derived therefrom, in my next paper.

Although I wish to reserve to myself the right of pursuing these investigations in a systematic manner, I trust others will take up the matter from their own particular standpoints, and report upon the method I have here propounded.

---

* The presence of ammonium salts, and of nitrates, I have found to be absolutely without influence; and this is also the case with chlorides when present only in small quantities; the other halogens are, however, detrimental. In my next paper I shall quote experiments in proof of the above statements, and show how the error arising from even large quantities of chlorides may be altogether prevented.

INFLUENCE OF MINUTE QUANTITIES OF SULPHURIC ACID ON THE ACTION OF WATER ON LEAD.

BY W. CARLETON-WILLIAMS, B.SC.,

Firth College, Sheffield

The action of dilute saline solutions on lead has been the subject of repeated investigations, but until recently the influence exerted by the presence of minute quantities of free acids on the solvent action of water on lead has been entirely neglected. The attention of Jarmain, A. H. Allen (*Chem. News*, 46, 145), and others, was first called to this subject by the numerous cases of lead poisoning which occurred in certain towns where the water supplied for household purposes is slightly acid.

Last year Mr. A. H. Allen and Dr. Sinclair White presented an interesting report on the prevalence of lead poisoning in Sheffield. The town is supplied with water collected on moorland, and is preserved in and distributed from two distinct set of reservoirs, A and B. The water from the two sources is almost identical in composition, as the quantity of chlorine, sulphuric acid, lime and magnesia is the same in each. The sole points of difference are that A contains 5·53grns. per gallon total solids (of which 0·47 is silica and 0·40 Al_2O_3), and has an acid reaction to litmus; whereas B contains 5·84grns. per gallon total solids (of which 0·65 is silica and 0·58 Al_2O_3), and is neutral to litmus. The water from the B reservoirs has no action on lead, but the feebly acid water drawn from the houses supplied from reservoirs A contains from 0·07 to 0·7grns. of lead per gallon.

The quantity of the free acid contained in the water from the A reservoirs is so minute that the authors were unable to ascertain its nature. They are of

opinion that it may be either sulphuric acid derived from the oxidation of the iron pyrites contained in the shale underlying the peat of the collecting ground, or organic acids derived from the peat.

The following experiments were made with the object of ascertaining the influence of minute quantities of free sulphuric acid on the action of dilute saline solutions on lead :—

Chemically pure lead foil was cleansed from grease by washing with alcohol and water, and was afterwards rubbed bright on a soft towel. It was cut up into pieces of 12·5 square centimetres area; each piece was rolled into a hollow cylinder, placed in a flask of about 150cc. capacity, and covered with 100cc. of the solution to be examined. A sheet of unglazed paper was placed over the flasks, in order to protect them from dust, and at the same time to allow free access to the air.

The distilled water used in preparing the solutions was aërated by shaking up with air, and also by repeatedly causing the water to trickle slowly from one vessel to another.

In order to estimate the amount of lead, 50cc. of the clear solution were taken, and the lead determined colourimetrically by means of sulphuretted hydrogen or ammonium sulphide. If the liquid was turbid it was necessary to filter it through asbestos, or, as this did not always prove effective, a stoppered bottle was filled quite full of the turbid liquid, and left at rest for 24 or 48 hours until the finely-divided suspended matter deposited. The numbers arranged in the table above represent the mean results of two or three determinations.

It appears from these results that the addition of 1 grain per gallon of sulphuric acid increases the solvent action of the dilute saline solutions on lead to a marked extent. The amount of lead in solution, as a rule, steadily increases until a point is reached where the solution begins to show signs of turbidity; this is alwaye accompanied by a decrease in the amount of lead in solution. The time which elapses before the solution becomes turbid depends not only on the nature of solution, but also on the physical condition of the lead, and on the temperature. It sometimes happens that the results obtained at different times, with the same solution and with lead from the same origin, give results which show a difference of from 0·3 to 0·45 grains per gallon, more especially in the case of the solution of sodium chloride and sulphate with free sulphuric acid. The lowest numbers obtained when sulphuric acid was present were always much higher than the highest readings obtained for the neutral solutions, so that there is no doubt that the presence of free acid increases the amount of lead in solution.

The total action of the solution on lead as distinguished from the amount of lead in solution, was estimated by exposing coils of lead to the action of 100cc. of the solution for 4 hours. The lead is brushed free from any deposit, and removed from the flask. A few drops of acetic acid were added to the turbid liquid to dissolve the basic salts of lead, and the amount of lead in solution was then estimated. The solutions containing free sulphuric acid remained clear for at least 24 hours. The results are, therefore, identical with those in the previons table.

These numbers show that the presence of 1 grain per gallon of free acid decreases the action of the dilute saline solutions on the lead, although it increases the quantity of lead dissolved.

Dr. Tidy brought before the British Association, at Birmingham, some interesting observations on the effect of silica in diminishing the action of water on lead. In the case of the Sheffield water supply, the water which attacks the lead contains 0·47grns. per gallon of silica, and the water containing 0·65grns. per gallon of silica has little or no action. Experiments were made to ascertain whether the presence of small quantities of silica diminishes the action of water on lead even when the water contains free acid. The results show that in certain conditions it is efficacious. A common lead pipe was filled with 100 cubic centimetres of solutions of calcium sulphate and free sulphuric acid (1 grain per gallon each) and left for 24 hours. The water contained 4mgs. of lead per litre. On repeating the experiment, with a similar solution, to which 2grns. per gallon of dialysed silica were added, no lead was found in solution. When ammonium nitrate was substituted for the calcium sulphate, the addition of dialysed silica diminished the action of the water on the lead. The results are quite different when strips of pure lead, which have been cleaned by immersion in dilute nitric acid, and thoroughly washed and rubbed bright, are exposed for 24 or 48 hours to the action of 100cc. of the solutions of the different salts (+ 1 or 5 grains per gallon H_2SO_4) used in the previous experiments. The addition of 2 or 4 grains per gallon of dialysed silica had no effect on the quantity of lead dissolved by the solutions containing free acids.

THE PURE CULTIVATION OF MICRO-ORGANISMS, WITH SPECIAL REFERENCE TO YEAST.

BY G. HARRIS MORRIS, PH.D., F.C.S.

THERE is no subject perhaps which has received greater attention during the last few years than the study of micro-organisms, and the various changes and actions which are produced by their agency. I propose to give you this evening some account of the methods which are employed for cultivating the various organisms in a state of purity—that is, in a state of freedom from all other organisms than the one we wish to study; and then to draw your attention to what has been done and is being done in connection with the pure cultivation of yeast, and its employment upon a practical scale. Klein,* in a lecture delivered before the Chemical Society, lays great stress upon the absolute necessity of working with pure cultivations. He says:—"Not till chemists come to look upon the matter in the same light in which we look upon it—namely, to obtain the organism pure, to render nutritive material sterile, to be able to produce with this pure organism the specific chemical activity you wish to obtain; not till you have fulfilled all these conditions, can you claim to have established the fact that a definite organism is the cause of a definite chemical change."

I do not intend this evening to say anything regarding the pathological micro-organisms, which are admirably treated of in Klein's "Micro-organisms and Disease;" although the methods employed for the cultivation of these are practically the same as those used for organisms which produce purely chemical changes, the only difference lying in the different nutritive medium employed for their cultivation.

Before all things it is necessary, in working with micro-organisms, to have a good microscope, capable of giving a magnification of from 300—400 linear diameters. This magnification is sufficient for all ordinary work; but in some cases it is, of course, an advantage to be able to examine growths under a higher power than the above. There are now so many makers of good, cheap instruments, that it is almost impossible to quote any special maker, but taking everything into consideration, the German makers, Zeiss and Seibert, supply as good an instrument at a lower price than English makers. I myself use one of Seibert's microscopes with No. IV. objective, and No. 3 eyepiece (this combination giving a magnification of 350 diameters), and fitted with an Abbé's substage condenser. For higher magnifications, Seibert's No. VI. objective, with the above-mentioned eyepiece, answers all purposes, a magnification of 950 diameters being given by this combination.

The media used for pure cultivations consist of both liquid and solid material. The former, in the case of pathological organisms, consists of different preparations of meat-broth, peptone, blood-serum, etc.; but for the organisms we shall consider to-night Pasteur's or Cohn's solutions or diluted beer-wort are more generally used.

Pasteur's solution consists of 10 parts pure cane-sugar, 1 part ammonium tartrate, and the ash of 1 part of yeast dissolved in 100 parts of water.

Cohn's solution is composed of 1grm. of ammonium tartrate, 0·5grm. potassium phosphate, 0·5grm. crystalline magnesium sulphate, 0·5grm. tribasic calcium phosphate in 100cc. distilled water.

The solid material used is a mixture of gelatine with broth, peptone, etc., or beer-wort. Koch, who introduced this solid mixture, used only 2—3 per cent. gelatine. But this mixture, although solid at ordinary temperatures, becomes liquid when the temperature is raised, and as in most cases it is necessary to carry on the growth at 25—30° C., or even higher, a larger percentage of gelatine must be added, varying from 6 to 10 per cent.

The vessels employed for pure cultivations consist of test tubes, Pasteur's flasks, Chamberland flasks, moist chambers, etc. One of the most important considerations in working with pure cultivations is, as Klein has pointed out, to obtain the apparatus and the solutions used in a perfectly sterile state. I propose, therefore, to briefly describe the precautions which it is necessary to take in order to ensure complete sterility of apparatus and culture material.

In the first place it is absolutely necessary that all vessels and apparatus, flasks, test tubes, beakers, filter papers, cotton wool, glass rods, etc., to be used, must be thoroughly sterilised by heating to 120—150° C., that is, at a temperature which is sufficient to kill all micro-organisms and their spores, which may have settled from the air upon and within the vessels. In the case of large vessels, such as flasks, this is best done by passing the flame of a Bunsen burner over the surface of the vessel until it is hot, and then immediately closing the mouth and side tube with sterilised cotton-wool and indiarubber tubing and glass rod. For small vessels, test tubes,

---

* Jour. Chem. Soc. 1886, 205.

beakers, cultivation chambers, etc., an air-bath heated to the required temperature is most convenient. This should be maintained at 120—150° C., and the vessels allowed to remain in it for 2—3 hours, at that temperature. The cotton-wool for plugging the mouths of flasks and test-tubes must also be well sterilised by being loosely pulled out and then heated in the air-bath to the above temperature for some hours, on several successive days. Filter-papers used for covering the cotton-wool plugs should also be heated in the air-bath. Forceps, pipettes, and all other odds and ends of apparatus must be sterilised by being passed through a Bunsen burner at the moment of use.

I have mentioned above the solutions most commonly employed for cultivations. These are rendered sterile and ready for inoculation in the test-tubes, and small flasks, in the following way:—The solid material, as broth gelatine, beer-wort gelatine, etc., must be poured into the previously sterilised flasks and test-tubes, whilst still in a fluid state, and then sterilised by being boiled twice or three times on successive days. Tyndall has pointed out that the spores of certain bacteria are not killed by boiling, therefore it is necessary to boil on successive days, in order to give the unkilled spores an opportunity of developing between each successive boiling, when, of course, the next boiling kills the developed organism.

No test-tube or flask, containing nutritive material, can be considered sterile until it has been kept at a temperature of 32—38° C., for at least seven days, without any sign of growth appearing.

This is of necessity a very brief sketch of the precautions which have to be observed, both in the preparation and sterilisation of culture solutions. A very complete and detailed description will be found in the little book by Klein, previously mentioned.

We will now pass on to the methods employed for obtaining pure cultivations of definite micro-organisms by inoculating the test-tubes and small flasks containing sterile material. We may roughly divide the inoculations into four classes.

1. Inoculations, by which it is required either to obtain an organism in a state of purity, which has previously been growing in a culture tube or other vessel, or to separate two or more organisms which were previously growing in the same vessel, and each of which we wish to obtain in a pure state. As an instance of this, I may take a hay infusion, which has been exposed to the air and then allowed to remain in a warm place. We should then have a mixed growth of two or more micro-organisms, each of which we may wish to isolate and study in a pure state.
2. Inoculations from animal fluids and tissues. This, however, relates solely to pathological organisms, and does not come within the scope of this paper.
3. Examination of water for micro-organisms.
4. Examination of the floating matter of the air.

In the first case we will suppose that we have an artificial cultivation in a test-tube, and that we desire to inoculate one or more sterile tubes with the micro-organisms contained in this cultivation. We then take a freshly drawn-out capillary pipette, slightly raise the plug of cotton-wool in the tube containing the cultivation with sterilised forceps, and carefully push the pointed end of the pipette through the loosened plug, until it reaches the growth in the tube; a small quantity of the latter then ascends the pipette, which is quickly withdrawn, the plug of cotton-wool again pressed down, and the minute drop of inoculating solution at once conveyed to a new culture-tube by exactly the same procedure as before—that is, the partial withdrawal of the cotton-wool plug, the insertion of the pipette with the solution into the sterile culture material, whether solid or liquid. A small quantity of the inoculating solution flows out of itself, or, if it does not, it may be forced out by a gentle pressure applied to the other end of the pipette. The pipette is then withdrawn, and the cotton-wool plug replaced as before. If more than one tube is to be inoculated, this operation is repeated, using, however, a fresh pipette for each inoculation. The freshly-inoculated tubes are then placed in a suitable support, preferably in a beaker on a cushion of cotton-wool, and placed in the incubator at the required temperature. If, however, we have a fluid—hay infusion, for instance—which a microscopical examination shows us to contain more than one organism, and we wish to obtain these in a state of purity, it is necessary to adopt either Kleb's method of "fractional cultivation," or the method of "dilution" employed by V. Nägeli and Lister.

The former consists in endeavouring to fractionate by successive cultivations the different organisms growing together in the same culture. It is effected by inoculating by means of a capillary pipette traces of the culture fluid into a series of new tubes, containing different nutritive materials; these tubes are then placed in the incubator at 35° C. for a short time, say 24 hours, at the end of that time it is probable that in some of the tubes the organism, which thrives best on the particular nutritive material contained in the tube, will have grown almost exclusively. The treatment is then repeated, and a series of fresh inoculations made from each of the first tubes. This is continued until the physical appearance, microscopic examination, etc., show us that we have a pure organism in our culture tubes.

The latter method, that of "dilution," consists in diluting the culture fluid containing the various species to a very large extent—varying from 1 in 1000 to 1 in 1,000,000—with a sterile saline solution, and then inoculating fresh culture-tubes with this diluted fluid. In this case it is possible that, owing to large dilution, only one species of organisms may be sown in some of the tubes, and a pure culture is at once obtained.

The two methods may often be advantageously combined by first making one or two cultures by the "fractional" method and then using this cultivation for "dilution" with sterile saline solution. If necessary this may be repeated until the desired pure culture is obtained.

In the examination of waters for micro-organisms, the plate method, originally introduced by Brefeld,[*] and later adopted by Koch for this purpose, is the one used. It has been so fully described recently in this Journal by Dr. Percy Frankland,[†] and also by Bischof,[‡] that it is unnecessary to refer to it at greater length.

With regard to the examination of the micro-organism in air, many methods have been suggested for collecting and cultivating these prior to their cultivation in a state of purity. The simplest method is to expose open flasks containing sterile nutritive material to the air in the desired locality for a certain time, and then to close them again. You have then in the flasks the organisms which were deposited from the atmosphere during the given time, and these can then be separated and examined. Using this method, Hansen examined[§] the atmosphere of various places within and around the brewery of Old Carlsberg at Copenhagen, and isolated a large number of organisms — yeast, bacteria, moulds, etc.

---

[†] This Journal, 1885, 608.

[‡] This Journal, 1886, 114.

[§] Compt. rendu du Laboratoire de Carlsberg, 1879.

Another method, proposed by Cohn and Mitlet,* consists in aspirating a given volume of air through a series of flasks containing sterile nutritive material, taking every care that no contamination can take place except from the aspirated air. The flasks are then placed in the incubator and the growths examined. A third method is that devised by Hesse,† in which a given volume of air is slowly drawn through a tube coated with nutritive gelatine, the micro-organisms are deposited on the gelatine and grow where they fall.

Such is a brief outline of the methods employed for obtaining pure cultivation of the Schitzomycetes or bacteria, as distinguished from the Saccharomycetes or yeasts. Apart from certain pathological micro-organisms, which have been thoroughly worked at in pure cultivation, we are almost entirely without sufficient evidence of the nature of the changes brought about by micro-organisms. Thus nothing definite is known of the organisms which produce lactic fermentation or the viscous fermentation of wine and beer; the butyric fermentation is also in a state of uncertainty. It is true that these, amongst others, have been worked at by Pasteur and other observers, but in all cases the results are vitiated by the fact that pure cultivations of the organisms were not employed. Another source of the frequent discrepancies between the descriptions of different observers is, I think, the failure to recognise the pleomorphism of micro-organisms which is well illustrated in the case of the acetic ferment. There are a great many statements which require investigation; for instance, *mucor racemosus* is said to be capable of producing alcoholic fermentation, but this statement is based upon very insufficient evidence, and requires confirmation by experiments carried on with pure cultivations of the ferment before it can be accepted. And this is only one of many statements of the same nature.

Hansen and other investigators have during the past few years examined morphologically and physiologically a considerable number of ferments in a state of purity, but it is only within the last few months that any advance has been made in the examination of the chemical action of these ferments, and the advance in the latter direction will be very slow until vegetable physiologists are also sufficiently chemists to be able to study the chemical changes taking place, or until chemists, working with organised ferments, adopt the method of pure cultivation which I have briefly described above.

I think we may consider that the researches of Adrian Brown,‡ alluded to above, on *Bacterium aceti* and *Bacterium xylinum* constitute quite a fresh departure in the investigation of the organised ferments. We have here not only pure cultivations carried out with every possible precaution, but also a quantitative examination of the fermentative action of the pure organism on certain definite sterile solutions. A brief outline of the researches will not be out of place here, since no better example can possibly be found of the treatment which must in future be applied to the chemical actions produced by micro-organisms.

Both *Bacterium aceti* and *Bacterium xylinum* were found growing on the surface of a beer which had been exposed to air. They were separated and purified by a combination of Kleb's "Fractional" and V. Nägeli's "Dilution" methods as described above. Both micro-organisms being strictly aërobic, and consequently requiring a free supply of air, flasks and test-tubes plugged with sterilised cotton-wool were employed for the cultivations. For the former the cultivating fluid was a 2 per cent. solution of alcohol in yeast water; for the latter claret diluted with half its volume of water and rendered acid with 1 per cent. acetic acid. When repeated cultivations showed that the organisms were pure, the action of the pure ferments on various *sterile* solutions was examined. *B. aceti* oxidises ethylic alcohol to acetic acid, together with a mere trace of a non-volatile acid, probably succinic: the acetic acid is further oxidised into carbonic anhydride and water by prolonged action; propylic alcohol is converted into propionic acid; methyl alcohol is unacted upon, although the ferment grows freely in a 1 per cent. solution in yeast water. Grown in Pasteur's solution with 2 per cent. dextrose and calcium carbonate, the ferment converts the carbohydrate in gluconic acid, which forms calcium gluconate with the calcium carbonate present; cane-sugar is unacted upon, but mannitol is converted into *levulose*, which, however, is itself entirely unacted upon by the ferment. This reaction is most important in helping to throw light upon the constitution of the carbohydrates. It also enables us to convert *dextrose* into *levulose*, since dextrose is converted into mannitol by the action of sodium amalgam, and mannitol into levulose by the action of pure *B. aceti*. *B. xylinum* is characterised by the remarkable fact that it converts dextrose, mannitol and levulose, more particularly the last, into *cellulose*. In its action on other substances it resembles *B. aceti*. It grows in the form of a tough gelatinous membrane, and is commonly known as the "vinegar plant;" this latter, however, is always mixed with yeast, which in the manufacture of vinegar from sugar solutions, first inverts and ferments the sugar, so forming alcohol for conversion into acetic acid by the ferment, since the pure ferment is without action upon sugar solutions.

I have ventured to quote thus fully from the two papers of Mr. Adrian Brown, as they are, so far as I know, the only instances of a quantitative chemical examination of the action of a pure organised ferment, and because the examination has brought to light some interesting facts connected with the action of such an every-day micro-organism as the acetic ferment.

I must now pass on to the more special part of my paper—viz., the pure cultivation of yeast, and its application upon an industrial scale. I suppose that we are all more or less familiar with the effect which Pasteur's celebrated work, "Etudes sur la Bière," produced upon the practice of brewing. It awoke brewers to the fact that upon their yeast depended the success or failure of their operations. But Pasteur chiefly directed their attention to the presence of ferments capable of setting up acetic, lactic, butyric, and similar fermentations, although he also pointed out the necessity of working with a yeast which was not contaminated to any great extent with "wild" yeast forms. Having had this danger so forcibly pointed out to them, brewers became alive to the absolute necessity of cleanliness in every part of the brewing plant, and I suppose that now the contamination to any great extent of brewing yeast with "disease" ferments, as distinguished from foreign yeast forms, is a thing of the past in all well-conducted breweries. With regard, however, to wild yeast forms, it is not so easy to know when they are present in a yeast, or to get rid of them when they are there.

We owe what will in all probability turn out to be the solution of the "wild" yeast question in our English breweries, as it has already done in the Continental breweries, to Dr. E. C. Hansen, of the Carlsberg Institute, in Copenhagen. He has applied the methods of pure cultivation to yeast, and has further so extended them as to be able to prepare pure cul-

---

‡ Jour. Chem. Soc., 1886, 172 and 432.

tures of yeast from a *single selected yeast cell.* When Hansen published in 1878 his investigations on the micro-organisms in air, referred to above, he remarked on the unsatisfactory state of the earlier work on the Saccharomycetes, and expressed his opinion that, in order to obtain a true knowledge of this class of organisms, it would be necessary to approach the subject from a different standpoint to that adopted by Reess* and Pasteur† in the work which they had already done. In 1881 he published the first of his researches in this direction—viz., that on "*Saccharomyces apiculatus*, and its circulation in nature," ‡ to which I shall again refer. In this he laid down the fundamental principle that investigations with the Saccharomycetes should be so carried on that each species could be cultivated from a *single* cell, in order to ensure the absolute purity of the cultivation, and ascertain the constant characteristics of the ferment. When this result could be obtained, we should have in our hands a method for the analysis of yeast, and not only would the results be of great scientific and theoretical interest, but they would also be of importance to the fermentation industries.

In his earlier work, above-mentioned, Hansen adopted a modification of v. Nägeli's "dilution" method, which was as follows :—A vigorous fermentation with the yeast from which it was desired to cultivate is promoted in a Pasteur flask ; the yeast formed is then largely diluted with a known volume of sterilised water, thoroughly mixed with the water by shaking, and the number of cells in a small drop of the water counted. The counting is effected by means of a hæmatimeter. This may consist either of a microscopic cover-glass on which a number of microscopic squares have been ruled, or of a microscopic glass slide, on which the squares are ruled in the centre of a very shallow cell. A good form of the latter is made by C. Zeiss, of Jena, in which the squares measure $\frac{1}{400}$th of a square mm., and the cell is 0·1 mm. deep, the cubical capacity, therefore, of each square, when the cover-glass is on, being 0·00025cmm. The drop is placed well upon the squares, which then assist the eye in counting the cells contained in the drop. Supposing 10 cells are found, then if a similar-sized drop is added from the fluid, which has again been thoroughly shaken, to a flask containing a known volume of sterilised water, say for instance 20cc., the probability now is that this 20cc. of water contains 10 cells. The flask is thoroughly shaken for some time, and then 1cc. of the liquid quickly introduced into each of 20 flasks containing nutritive solution ; there is now in all likelihood 1 cell in each of 10 of these 20 flasks. This is of course only a probability. In order to be sure that some of the flasks contain only one cell, it is necessary to allow them to remain until a growth appears. Directly after adding the 1cc. of the diluted yeast to the flasks, they are thoroughly shaken and placed in the incubator at the required temperature, the cell or cells present then sink to the bottom of the flask, remain and grow where they settle, which, in the latter case—*i.e.*, if more than 1 cell is present—is probably at different points on the bottom. After some days the flasks are carefully examined, and the points of growth noted. In those flasks in which there is only one speck of growing yeast visible, the inference is that it proceeds from one cell, and consequently the flask contains a pure cultivation ; in other cases it is possible that two or more specks are visible, then it is safe to conclude that more than one cell was sown in the flask, and its contents are consequently rejected.

This method has yielded good results in Hansen's hands, especially with ferments which have some distinguishing characters, such as *Sacch. apiculatus.* This method also gives much better results than the one about to be described when it is wished to separate weak and strong yeasts, which are growing together in a nutritive liquid. Another point in its favour is the complete absence of any possibility of outside contamination after the 1cc. of diluted yeast has been added to the flask.

Hansen, however, afterwards adopted a solid medium for his cultivations—viz., hopped wort and gelatine ; and he gives the preference to this material, except under the circumstances mentioned above, since it enables the experimenter to directly observe the individual cells under the microscope, and to follow the course of their development. He adopted a modification of Koch's gelatine plate method, taking, however, more elaborate precautions to prevent contamination after the inoculated gelatine is spread on the plate. Before proceeding to describe the method in detail, it will be as well to point out the necessity of having some place set apart entirely for pure cultivation work, as the success or failure of these operations depends greatly upon the freedom of the air from germs at the time the experiments are being carried out. For this reason, the room should be allowed to remain perfectly undisturbed for some hours before the cultivation is made, in order to allow the dust to settle.

In order to prepare a pure cultivation of yeast, we take a growth of young and vigorous cells, dilute this down very largely with sterile distilled water in a small Chamberland flask, until the proper dilution is reached (this is ascertained by a microscopic examination), and then again dilute a drop of this with sterile beer-wort gelatine (hopped wort of about 1058 sp. gr. with 5—10 per cent. gelatine), until we have an extreme dilution. A drop of this is then withdrawn with a sterilised glass rod, and spread upon the under side of a thin cover-glass, which is then quickly placed on the ring of a Böttcher's moist chamber. Fig. 1 represents one of the chambers in question ; *a* is the thin cover-glass, with a layer of gelatine on its under surface *b*, and placed on the glass circle *c*, which is 30mm. in diameter, and cemented to the glass slide ; *d* is a thin layer of sterile distilled water. Fig. 2 shows the Chamber-

land flask mentioned above: it consists of a flask on the neck of which a cap has been ground with emery; one end of the cap is drawn out, and this end is closed with a plug of sterilised cotton-wool.

The inoculated gelatine having been spread on the glass circle and allowed to set, the chamber is then placed on the stage of the microscope and examined. One or two well isolated yeast cells are picked out, and the position of these marked on the glass circle by a marker of some description. The whole is then placed in an incubator at about 25–30° C. and allowed to remain for a day or two. At the end of about two days the growths are generally visible to the naked eye, and appear as small whitish specks about the size of pins' heads. These specks should be well separated from each other on the glass circle

When the specks have attained a sufficient size they are transferred to sterile hopped-wort, of about 1·058 sp. gr., contained in Pasteur's flasks (Fig. 3).

FIG. 3.

These consist of flasks with the neck drawn out and bent over, as shown in the figure, and with short side-tubes, which are closed with a piece of indiarubber tubing, and a glass rod; the bent tube is closed with a plug of sterilised asbestos. The transference is effected by quickly lifting the cover-glass with the colonies, plunging a short piece of sterilised platinum wire into the colony, and then immediately dropping this into the side-tube of the flask, the glass-rod stopper being quickly withdrawn and replaced. Having got the colony *which we know is derived from one single cell* into the flask, we are then in a position to study its characters and properties. Fig. 4 shows another form of flask, which is often of great service, the mouth of which is closed by two layers of sterilised filter-paper.

FIG. 4.

The above is of necessity only a brief outline of the operations to be performed and the precautions to be observed, since it is impossible in the scope of this paper to enter fully into details.

[Dr. Morris, in the course of the paper, gave a practical illustration of the manipulations necessary, and showed moist chambers with colonies in various stages of growth.]

Such is the process which Hansen has employed to effect a revolution in the study of the Saccharomycetes. By its means he has succeeded in separating a number of apparently different species of yeasts, from which he has selected six for further study. In addition to these he has isolated two varieties of ordinary bottom-fermentation yeast, which are at present used in the brewery of Old Carlsberg, and also in a very great many other breweries on the Continent, and to which I shall again refer. He has also determined that the form, the limits of size, and the appearance of the cells do not remain constant for each variety or species, but are influenced by different conditions of growth. The form and phases of development of the cells, however, when viewed from another standpoint, give very important differences for each variety. This is the case when the cells of the different varieties are exposed to similar conditions, as in the ascospore and film formations; it is found then that the different yeasts behave in a very different manner, and each species gives well-defined characteristics. This can only be explained by the supposition that the different varieties or species have distinct innate properties.

We will now proceed to consider the differences which Hansen has found between the different varieties of yeast. He has, as stated above, differentiated six species of yeasts, which he calls—

Saccharomyces cerevisiæ, I.
Saccharomyces Pastorianus, I., II. and III.
Saccharomyces ellipsoideus, I. and II.

The ordinary sedimentary forms of these are shown in Figs. 5 to 10: Fig. 5 being *S. cerev.* I.; Fig. 6, *S. Past.* I.; Fig. 7, *S. Past.* II.; Fig. 8, *S. Past.* III.; Fig. 9, *S. ellip.* I.; and Fig. 10, *S. ellip.* II. It will be seen that although the varieties taken separately appear quite distinct, yet if they were mixed it would be extremely difficult to detect one from the other—for instance, the *S. Past.* when mixed with *S. cerev.*, or the *S. ellip.* when mixed with *S. Past.* or *S. cerev.* The size of the cells varies considerably with the species.

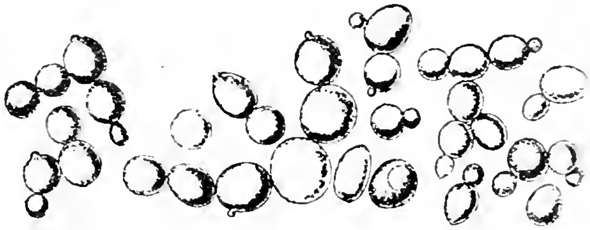

FIG. 5.

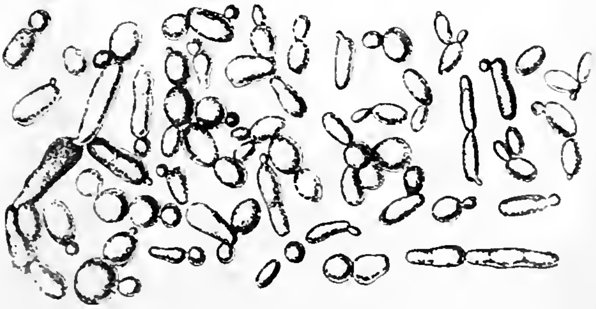

FIG. 6.

Fig. 7.

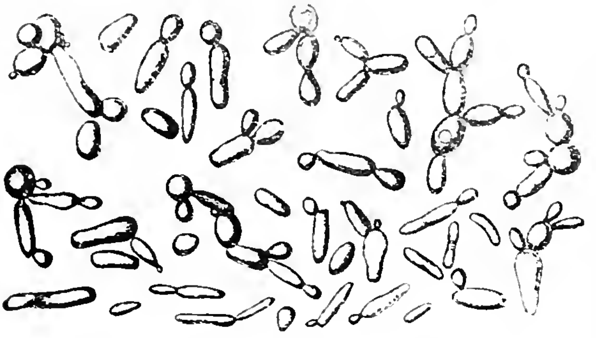

Fig. 8.

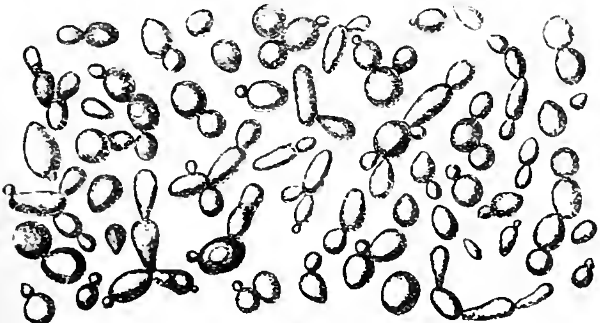

Fig. 9.

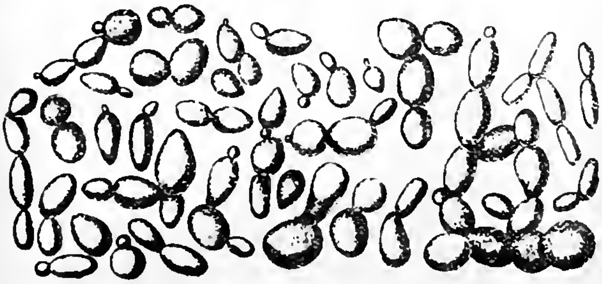

Fig. 10.

The characteristic which Hansen chiefly relies upon in differentiating these species is the ascospore formation. The formation of ascospores in yeast cells has long been noticed, Reess, Engel, and several other observers having described it, and attributed this formation to various causes. Reess built up a system of the Saccharomycetes based upon the form and size of the cells and spores. Brefeld concluded that only "wild" or "natural" yeast was capable of giving spores, whilst cultivated yeast had lost this property. Hansen[*] examined his six species for this formation as follows: A small quantity of the yeast was spread on a sterilised gypsum block, this block was then placed in a flat covered glass dish, and was kept moist by filling the latter half full of water. The formation was then generally seen when the dish had stood for a few days at the ordinary temperature. The spores generally form as round bodies within the cell, and are usually accompanied by the "sheath-wall" formation. Fig. 11, page 120, shows the formation for the six species. Hansen investigated the influence of different temperatures upon the rate of formation of the spores, in order to determine whether the different species could be distinguished from each other in this way. For this purpose it was necessary to know—

1. The limits of temperature—*i.e.*, the highest and lowest temperatures at which spores were formed.

2. The most favourable temperature at which the spores were formed.

3. The ratio of the intermediate temperatures.

The results obtained (which are given in Table I.) showed that the formation of spores proceeded very slowly at ordinary temperatures, but more rapidly as the temperature rose, until it reached a certain point. When this point was passed, then the formation again decreased, until it at last ceased entirely. The lowest temperature found for the six species was ½—3° C.; the highest 37·5° C. The highest and lowest temperatures for the different species were also different, and also the limits of temperature within which the ascospore formation takes place in the different species. We see from the table that the differences at the high temperatures, and down to 25° C., are almost inappreciable; but when we lower the temperature the differences become more marked. For instance, at about 11° C., *S. cerev.* first shows ascospores at the end of ten days, whilst *S. Past.* II. shows them at the end of seventy-seven hours, and so on with the other species. In making this comparison, it is necessary to make the experiments with each of the six species under exactly the same conditions, since the use of old or young cells, composition of the nutritive medium, etc., exercise a marked influence on the temperature and rate of formation of the ascospores.

Upon these results Holm and Poulsen[†] have based a method for the practical analysis of brewing yeast. Hansen found that the ordinary bottom-fermentation yeast only formed spores at 25° C. after some days, whilst, as we have seen, the "wild" forms, as exemplified by the six species we are considering, form ascospores at this temperature in a few hours. Working with pure cultivations of each species, Holm and Poulsen found that they were able to detect 0·5 per cent. of *S. Past.* I. and III., or *S. ellip.* II., in a mixed yeast; and, as Hansen has shown, that when these "wild" yeast forms, which are the cause of the diseases in bottom-fermentation beer, are present in a barm to the extent of not more than 2·5 per cent. of the total yeast, they do not develop their particular form of disease; it will be seen that, for bottom-yeast at least, the ascospore formation forms a valuable means of determining the purity of a barm.

The next and most recent of Hansen's observations are those on the "film" formation.[‡] The formation of films on the surface of the culture-liquid is peculiar to most micro-organisms when the greater portion of the food-stuff contained in the liquid is consumed. As the result of a series of exhaustive experiments with the six foregoing species, Hansen has established differences in their film formations, both as regards

[‡] *Ibid.* 1886.

the limits of temperature within which it is possible for a growth to take place, and also in the appearance of the cells of the film; whilst, as a general rule, all the cells of old films show a remarkable change of form, large mycelium-like cells in ramified colonies being formed, yet the cells of *S. cerev.* I., *S. Past.* II., and *S. ellip.* II. in a young state show no mycelium-like colonies. *S. Past.* I. and III., and *S. ellip.* I., however, (13—15° C.) show very marked differences, and allow the various species to be easily distinguished. *S. Past.* II. and *S. Past.* III., which are both top fermentation forms, and the cells of which are very similar under ordinary conditions, show a marked difference at this temperature. Fig. 12 (p. 121) shows the various forms of the cells of the films of the six species at 13—15° C.

show them very early. Table II. shows the temperatures and the length of time necessary for the formation of the films of each of the six species. At the high temperatures there is very little difference in the forms, excepting in the case of *S. cerev.* I. and *S. ellip.* II.; but the young films at lower temperatures

These are the principal scientific results obtained by Hansen in his researches on the morphology and physiology of pure cultivation yeasts. It is an open question how far these different yeasts can be considered to represent distinct species, since it is at present a moot point where the bounds can be drawn between species and varieties in the Saccharomycetes. On this account Hansen has preferred to give his yeasts the above distinguishing numerals instead of re-naming them, leaving this latter until more is known on the subject.

Jörgensen has recently published a book on "Die Micro-organismen der Garungsindustrie," in which he attempts a classification of the Saccharomyces. In this he sums up Hansen's six species as follows :—

Saccharomyces Cerevisiæ I.—A top-fermentation yeast, giving excellent results in practice ; used in the breweries of London and Edinburgh in an impure state ; develops ascospores at temperatures between 11—37° C. ; film formation at 13—15° C.—the predominant number of the cells resemble the original yeast (Fig. 12, *a*).

Fig. 11.—Ascospore Formation (after Hansen) × 1000.

1. *S. cerev.* I. 2. *S. Past.* I. 3. *S. Past.* II. 4. *S. Past.* III. 5. *S. ellip.* I. 6. *S. ellip.* II.

Saccharomyces Pastorianus I.—Gives a bitter flavour to beer ; develops ascospores at temperatures between 3° and 30·5° C. ; film formation at 13—15° C.—fairly numerous, strongly-developed mycelium-like colonies of very elongated sausage-shaped cells (Fig. 12 *b*).

Saccharomyces Pastorianus II.—Causes no disease in beer ; develops ascospores at temperatures between 3° and 28° C. ; film formation at 13—15° C.—oval and round cells predominant (Fig. 12, *c*).

Saccharomyces Pastorianus III.—Cause of yeast-turbidity in beer ; develops ascospores at temperatures between 8½° and 28° C. ; film formation at 13—15° C.—strongly-developed colonies of sausage or thread-shaped, mycelium-like cells (Fig. 12, *d*).

Saccharomyces Ellipsoideus I.—Yeast of grapes ; develops ascospores at temperatures between 7·5° and 31·5° C. ; film formation at 13—15° C.—greatly ramified and strongly-developed colonies of short and long cells ; ramifications often forked (Fig. 12, *e*).

Saccharomyces Ellipsoideus II.—Cause of yeast-turbidity in beer ; develops ascospores at temperatures between 8° and 34° C. ; film formation at 13—15° C.—resembles the ordinary form in a marked degree (Fig. 12, *f*).

In addition to these, various other yeast forms have been described by various observers—viz., *S. exiguus* (Reess), *S. minor* (Engel), *S. conglomeratus* (Reess), and so on, but they have not yet been put to the test of pure cultivation.

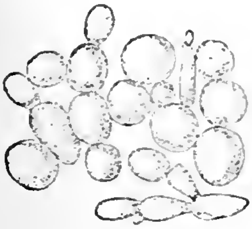

Fig. 12*a*.

Fig. 12*b*.

Fig. 12*c*.

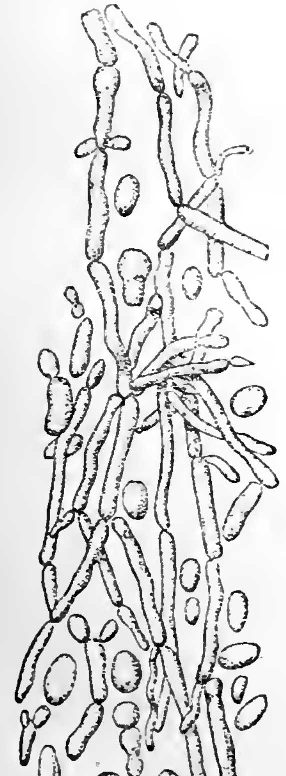

Fig. 12*d*.

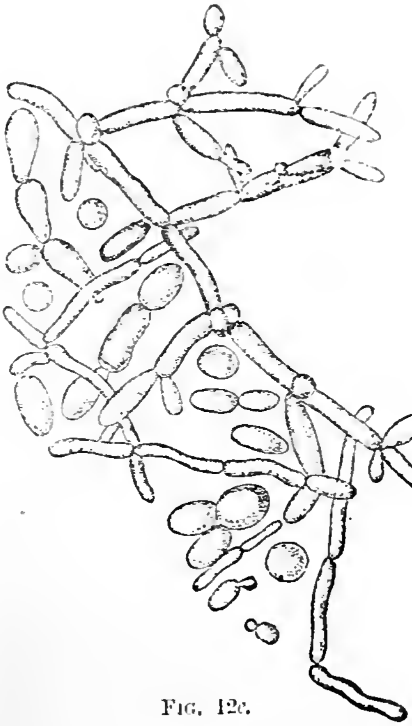

Fig. 12*e*.

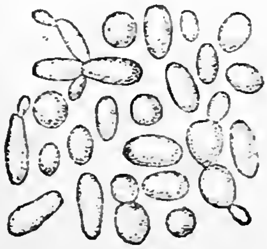

Fig. 12*f*.

There is another yeast form, to which I have alluded — viz., *Saccharomyces apiculatus*, which possesses great interest on account of its being the only alcoholic ferment whose cycle in nature has been exactly determined, and since it formed, as already stated, the starting-point in Hansen's researches on the yeasts. It lends itself especially to this purpose, since it has a peculiar shape which is possessed by no other yeast. It forms typical citron-shaped cells (shown in Fig. 13), which do not yield endogenous spores, and, therefore, correctly speaking, it does not belong to the genus Saccharomyces. The ferment is found upon all ripe succulent fruit, in the yeast of wine, and also in the spontaneously fermented Belgian beer. *S. apiculatus* is a bottom-ferment which is capable of setting up alcoholic fermentation in beer. The fermentation is, however, slight, only 1 per cent. alcohol being formed instead of 6 per cent.

formed by *S. cerevisæ* under similar conditions. The explanation of this is, that it does not ferment maltose, and does not secrete any invertase. In dextrose solutions it sets up a vigorous alcoholic fermentation. Microscopical examinations of ripe, succulent fruit in summer show that this ferment is present in considerable quantity in a healthy budding condition; on the unripe fruit, leaves, etc., it is not found, and no trace of the ferment can be found upon the plants in the winter. Hansen has, however, shown that the ferment hibernates in the earth under the trees, and in early summer is carried again into the air and on to the ripe fruit by the action of the wind and insects.

FIG. 13.

S. apiculatus compared with *S. cerev.* (after Hansen) × 950.

Now, what have been the practical results of this work of Hansen? I have already mentioned that pure cultivation yeast is in use at the Carlsberg breweries. In 1883 Hansen, having had occasion to study the causes of some cases of yeast-turbidity, came to the conclusion that the only real remedy for diseases of beer caused by "wild" yeast was to work in all cases with yeast which could be guaranteed free from these wild forms. This can only be done by Hansen's method of pure cultivation or some modification of this method.

Hansen* succeeded in isolating from the beer which was submitted to him, by the method I have described, three varieties of yeast—*Sacch. cerevisæ* (ordinary bottom-yeast, which constituted the greater portion), *Sacch. Pastorianus* III. (a form of bottom-yeast), and the *Sacch. ellipsoidens* II. (a form of top-yeast). Experiments carried out with the pure yeasts showed that fermentations with the *S. cerev.* gave a beer which was quite free from any form of disease, but that when either one or both of the other forms were also used in the proper proportions, the disease was set up. Further experiments showed that the yeast-turbidity was not caused if the two "wild" yeasts were not added until the end of the primary fermentation, and also that the disease did not show itself if *S. Past.* III., or *S. ellip.* II., formed 2·5 per cent. only of the yeast used for pitching, and when the fermentation was carried on in the fermenting cellar until the beer showed an attenuation of 6·7° Balling, and when the resulting beer was stored for at least three months. If, however, the attenuation was not run down so low as this, and the storage not continued so long, the disease showed itself with the above proportion of "wild" yeast.

The result of these experiments was that Hansen cultivated two varieties of bottom *S. cerev.*, for use in the Old Carlsberg Brewery, which are known as Nos. 1 and **2**. These yeasts, which, under the microscope, appear to the uninitiated to be identical, give very different results in practice.

No. 1 gives a beer well adapted for bottling, and containing less CO_2 than No. 2. The beer should remain bright in bottle for at least three weeks; it has also a lower attenuation than No. 2. This yeast is chiefly employed for home use.

No. 2 gives a good draught beer, containing more CO_2 than No. 1; it is not adapted for bottling, and is much preferred by German brewers to No. 1, and is, therefore, chiefly cultivated for export.

Now, a word as to the cultivation of pure yeast upon a sufficient scale to barm brewery vessels. I have shown you that it is comparatively easy with experience and a rigid adherence to the small precautionary details, to obtain a small quantity of pure yeast, but then the question arises—How are we to carry on the cultivation under conditions of purity until we have sufficient pure yeast for our fermenting-square? Well, at Carlsberg it is done by transferring the yeast from a small flask to a number of larger flasks, and when the growth of yeast is over, dividing the yeast in these between a still greater number of larger flasks, taking care, of course, to use all due precautions, as many as 50 1½ litre Pasteur's flasks being used for the last laboratory cultivation. This, however, only gives about 2 pounds of fairly thick yeast. It is then necessary to work with still larger vessels; this is done in the brewery, and as, fortunately for the Danish brewers, they are not hampered by any excise regulations in the breweries, they are able to arrange small fermenting rounds in such a way that they can collect in them sterilised wort, and after adding the yeast, lock the vessels up and adopt means to prevent air contamination.

The employment of these pure yeasts is coming very largely into use in the beer-drinking countries of the Continent, and some of the most noted brewing technologists have given it their support, notably Jacobsen, Aubry, Marz, Lintner, etc. The latter sums up the question in the following statements:—

1. By contamination with so-called "wild" yeasts, an otherwise normal brewery yeast can be rendered incapable of producing a beer of good flavour and with good keeping properties.
2. A contamination with "wild" yeasts may be produced by the dust of the air during summer and autumn, by the malt, or other sources.
3. By employing Hansen's method of pure cultivation and analysis, it is possible to obtain from a contaminated yeast a good brewery yeast in a state of purity.
4. Yeast cultivated in a state of purity possesses in a marked degree the properties of the original yeast before contamination, as far as concerns the degree of attenuation, the flavour, and keeping properties of the beer.
5. There exist different varieties of normal bottom yeasts *(S. cerevisæ)*, each with special properties, which like the peculiarities of species are maintained constant.

It must, however, be added that the method is not without its opponents, Delbrück and Hayduck, of Berlin, being the chief. These consider that yeast can be purified by cultivation in a saccharine solution of hops, and that all bottom yeast *(S. cerev.)* belongs to one species, the differences in behaviour which are noticed being merely transitory.

So far, all that has been done with pure yeast relates entirely to bottom yeast, with the exception of a few top-fermentation breweries on the Continent, particularly in Denmark, for which Jörgensen has cultivated a pure top yeast. Nothing has yet been done in England in this direction, although experiments upon an industrial scale are now being carried on at Burton-on-Trent with different species of pure yeast. We, however, in England labour under a variety of difficulties from which the Continental

---

* Zeitschrift f. das gesammte Brauwesen, 1883, 177.

brewers are exempt, such as temperature of fermentation, conditions of storage and of consumption of the beer.

Sufficient has, however, already been done to prove that in ordinary brewery yeast we also possess a mixture from which, by Hansen's method, several varieties of *S. cerev.* can be separated, which cannot microscopically be distinguished from each other, but which, when used upon a practical scale, give entirely different results, both as to flavour, brightening, attenuation, and mode of separation of the yeast. Experiments have also shown that these characteristics can be maintained unimpaired throughout a very great many successive fermentations in the brewery.

With regard to the scientific aspect of the question, the pure cultivation of yeast opens up an immense field of work. Attention has already been drawn by Mr. Horace Brown and myself to the different behaviour of what are usually called "secondary" forms, to the various constituents of malt-wort; this is a question which can only be studied by means of pure cultivations of the various yeast forms, and I trust that before long we shall have something more to say on this subject. Then there is the question of the products of alcoholic fermentation; all the work which has been done on this subject by Pasteur and others requires to be repeated with pure yeast, for we cannot too strongly insist upon the fact that, although Pasteur's celebrated work paved the way for all that has been since done, and his methods of working for the prevention of outside contamination are still used, yet he had not the initial purity of his yeasts which we can now get. Any general condemnation of the value of Pasteur's work, such as has been recently passed upon it by certain German investigators, cannot be too strongly protested against, since his almost unrivalled accuracy of experiment and scientific method of work formed the basis on which all subsequent experiments have been based.

As instances of the value of investigations with pure yeast, I may quote the following recent researches:—

Borgmann* has lately shown how largely the use of pure yeast modifies the products of fermentation in one important particular. He has made analyses of a large number of ordinary lager beers, and finds that the proportion of alcohol to glycerin in these varies between a maximum of 100:5·497, and a minimum of 100:4·140; whilst analyses of pure Carlsberg beer, fermented with Nos. 1 and 2 yeasts, gave the proportion 100:2·63 for the former, and 100:3·24 for the latter.

Ordonneau † has shown also that a potato-spirit mash, when fermented with beer yeast, gives amongst the products isobutyl alcohol, whilst when fermented with *S. ellip.*, the natural ferment of wine and eau-de-vin, normal butyl alcohol is formed, and that the unpleasant flavour of artificial spirit is due to the former alcohol, fermentations of *S. ellip.* giving spirit with the pleasant aroma and flavour of natural cognac.

The Fourth Meeting of the Fourth Session of this Section was held in the Rooms of the Chemical Laboratories of the University of Edinburgh, on Tuesday, February 1, 1887.

PROFESSOR CRUM BROWN, M.D., D.SC., F.R.S., IN THE CHAIR.

CHAIRMAN'S OPENING REMARKS.

Professor Crum Brown said he had much pleasure, on behalf of the Chemists of Edinburgh, in welcoming the Section there. He was sure that many of them knew the fact—and he thought it right to say it now—that they owed this meeting greatly to Mr. Irvine, whose zeal for the progress of the Society—not only in this part of Scotland, but for the Society generally—had induced him to move in this direction. When the proposition was at first mooted, a feeling seemed to exist that attempts of this kind were hazardous, but now that it had taken place he thought it would be admitted by all that the step was a right one. He hoped that the Society would find that they were able to have a good meeting in Edinburgh, and that by-and-bye they might see their way to have more regular and stated meetings in that city, as well as perhaps in other parts of Scotland.

◆

ON PARAFFIN SCALE TESTING.

BY D. A. SUTHERLAND, F.C.S.

The estimation of the percentage of impurities in paraffin scale of commerce is one of great monetary importance, and being to a certain extent merely an arbitrary or comparative test, is the cause of frequent disputes. At all times should the particular test be one agreed to by the parties concerned, and specified in the contract.

Somewhat recently I have had occasion to test a large number of samples. Despite every care in testing, in a room where the temperature can be maintained for a considerable time at 60° F., my results seldom agreed with those of the buyer—a contingency, however, not always inseparable from a falling market. That my results were accurate according to the method I used, was proved on repeated arbitration by the public analyst, whose method it was. But the buyers were still unsatisfied, and adhered to their own results.

The differences were not of 0·02 or 0·04 per cent., which would be of serious importance in the assay of pig iron for sulphur or phosphorus; but differences ranging from one to three per cent., which, on a valuable product like scale at £25 to £30 per ton, is of no little importance.

Acting on advice, I inquired into the methods of testing. No two appeared to me to use exactly the same test, but I proceeded to try them *seriatim* to ascertain the difference by the same operator. While doing this, it occurred to me, that as they are not all mentioned in any publication, it might be better if they saw the light, and that a timely discussion on their merits might result in the survival

---

* Zeits. Anal. Chem., 25, 532; this Journal, 1887, 47.
† Compt. Rendu., 1886, 217.

of the fittest, or the evolution of a better. To make the point interesting to those who may not be familiar with the subject, I would briefly explain that the scale (hard scale) referred to, is obtained by cooling the heavy oils from petroleum or shale oil, filtration to separate the oil, and subsequent hydraulic pressure.

I have on the table a sample of paraffin scale as it comes from the press.

Scale is of value to the refiner and candlemaker, only for the wax it contains of a melting point higher than that of the ordinary temperature. Consequently he makes a claim upon each delivery for water and dirt contained, and for what he terms oil, which, however, consists mostly of soft paraffin held in solution.

The claim is generally allowed up to 6 per cent., being less in summer, or when weather is warm; and greater in winter time and cold weather, when the cooling power is greater, and a corresponding increase of soft paraffin is extracted.

The oil (so-called) is universally extracted by pressure, at 60° F., in a press provided with a plunger and cup, 5⅞in. diameter.

The powdered scale is placed between two circles of cloth, so many circles of filtering or blotting paper placed on each side, and the pressure applied.

Here, however, the analogy terminates, for different weights of substance are used, and different amounts and duration of pressure applied; in the case of the plunger and cup on the table by means of a screw with a cross-head lever, four feet long, in other cases by a spiral spring or by a long lever with a weight on the end. Of the melting point I do not propose to speak, though the results vary also according to the method used. Mr. A. H. Allen* has, in his very valuable book, given a description as complete as possible of the various methods.

Sampling.—I would like to say in passing that this, as in all tests, is most important. Scale is usually conveyed in tierces such as are used for sugar, and samples drawn two weeks or so after casks have been exposed to wet weather show at least a gain of one per cent of water.

Mr. Boverton Redwood has given the most valuable communication on the subject in his paper, read before this Society, "On the Determination of Oil in Scale,"† and I cannot do more than refer to his conclusive experiments given there, which prove that the amount of pressure is not of so much importance as the length of time it is applied, and that the temperature of the press and sample must be exactly 60° F.

He again refers to this point in his very comprehensive Cantor Lectures (1886) on "Petroleum and its Products," and gives some further experimental results.

Mr. A. H. Allen's work, already referred to, quotes Mr. Redwood, and gives two methods for water estimation.

The following processes are in use at present:—

METHODS BY DIRECT PRESSING OF SCALE.

I.—(*a*) 16grms. (250grs.) pressed (pressure of two men, one at each end of lever), at temperature of 60° Fah., with five circles each side for two minutes; removed, replaced with two circles each side, pressed for ten minutes. Loss = oil and portion of water (*a*).

(*b*) The pressed cake is dissolved in gasolene in a tared beaker, settled, decanted, washed with gasolene, the gasolene is almost entirely decanted after the last washing, and the remainder is evaporated at the ordinary temperature till the weight remains constant. Weight = water and dirt in pressed cake. Dried in water-bath, re-weighed. Loss = water, weight = dirt.

(*c*) Water and dirt in similar manner in 10grms. of original sample. Results expressed in percentage and calculated (*a*) + (*b*) − (*c*) = oil.

II.—*Oil:* (*a*) 32grms. (500grs.) pressed at 60° Fah. (nine tons pressure) between sufficiency of circles for five minutes. Loss = oil.‡

(*b*) *Water.*—25grms.§ maintained at 230° Fah. and stirred with a thermometer till weight constant, or done similar to III.

(*c*) *Dirt.*—Scale dissolved in petroleum spirit, filtered through tared filter, washed well with spirit.

METHODS WHERE WATER IS FIRST SEPARATED.

III.—Scale is melted in a 1000 grain graduated cylinder, and allowed to settle in warm water, scale decanted, residue shaken up with shale naphtha, settled, and percentage of water read off at 60° F.

IV.—1000grs. (64grms.) taken, melted and settled in beaker flask, decanted, residue washed with shale naphtha, and finally treated with gasolene as in I. (*b*). This method is used to check I. and III.

IV.—1 or 2lb. are heated in a copper still, vapours led through condenser, water collected in graduated cylinder. Dirt as in II. (*c*).

In III. and IV., oil is determined in scale poured off, and in V. in scale left in the still.

A sufficiency is poured into a tin dish, cooled directly by some operators, by others slowly in a water-bath overnight.

32grms. (500grs.) are taken and pressed as in II.

The latter methods are most frequently used, but the time of pressing is by no means the same, varying from 5 to 20 minutes.

It is claimed for them that some scales are "doughy" and will not bleed out the oil they contain, unless re-melted and allowed to cool slowly to ensure perfect crystallisation.

Differences of no less than 4 per cent. in oil alone between a sample done this way and one done by direct pressure have been quoted to me, though personally I have not had opportunity to prove this highly probable theory. In all cases I found little or no difference.

Method III. is very open to criticism; it is impossible to read in so wide a tube as is generally used nearer than 0·5 per cent. Moreover, it is held by Dr. Wallace, city analyst, Glasgow, that the insoluble may be bulky, and so be a source of error. He says, in a letter received by me this morning, "We have found the method of testing water by melting and settling very unreliable, when the percentage of water is small, and the insoluble bulky." Dr. Wallace had only received the abstract of my paper yesterday, and consequently had not time to say more.

Some experiments done with the same sample of scale by the different methods for water and dirt, showed rather lower results by method I. than by the others, due, no doubt, to partial evaporation in so small a quantity, a loss of 0·09grm. being equal to 0·9 per cent., while IV. and V. compared favourably with the tube method (in a narrow tube); the percentage of dirt in 20 samples only averaging 0·15 per cent.

The experiments done for per cent. of oil by the methods varied according to time of pressing, etc. 8000grs. also of a sample were melted, allowed to settle, and clear scale poured off to cool. The scale was used at leisure moments for various experiments. Portions of the sample were pressed for various lengths of time; the results were constant when the conditions were the same, three tests, at 5 minutes pressure, not differing by more than 0·2 per cent.; longer pressing or less scale used for test gave results which were analogous to those of Mr. Redwood,‖ and tended to show that the time, *five minutes*, laid down

† This Journal, 1884, p. 430 *et seq.*

‡ This Journ. 1884, p. 430.

§ Soc. Arts. Cantor Lectures, p. 57.

‖ This Journ. 1884, p. 431.

by him, after careful experiments and consideration, is the most just and fair.

Other experiments with samples maintained, previous to weighing, at 45°, 65°, and 70° F., showed similar results, showing attention must also be paid to the temperature of the sample.

Since receipt of Mr. Redwood's letters, I have added that experiments were also done with various qualities and quantities of absorbent paper; grey filter, botanical bibulous, and white blotting paper, all of which are in use. The results showed slight but distinct differences.

Experiments were made with circles of coarse and fine linen and cotton with like results.

What has to be settled then is—Which is the most accurate method of estimating the water and dirt? For the oil—Temperature of press and sample, length and approximate amount of pressure, amount of sample to be used, the number of circles of paper, the character of the cloths and paper.

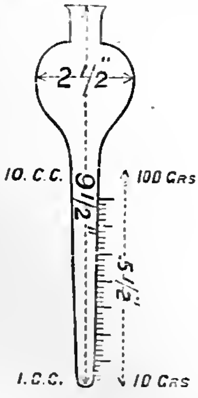
Until a universal method be adopted this test must remain unsatisfactory, and be the source of much friction between buyer and seller, who at present talk quite freely of the test of some one analyst being always 2 per cent. higher than that of another, or *vice versâ*.

It is my object *merely* to draw attention to this anomaly, and to the necessity for union and compromise on this point, so that a fixed process may be laid down for general adoption, which I trust will be done by those more qualified from knowledge and experience than myself.

At the same time I may be permitted to mention the process I have adapted from the foregoing till the uniform test be agreed on.

Water and Dirt.—Finding a very long 1000-grain tube troublesome to fill, I have had a tube made with a two-fold object—to save time in filling and melting, and to minimise error in reading of meniscus.

A tube with a top like that of a separator, wide mouth $\frac{3}{4}$in. diameter, neck 1in. long, bulb pear-shaped, terminating in small tube $\frac{3}{8}$in. diameter and 5 to 6in. long, graduated in $\frac{1}{10}$cc., or grains 1 to 100; the whole tube holding about 1500grs.*



64grms. (1000grs.) is weighed out, introduced into tube; tube being held by neck with burette clamp and immersed in water at 150° F. till scale melts and dirt is settled (it requires a little tapping). The bottom portion is solidified by immersion in cold water, and as much as possible of scale is poured off to cool; the residue shaken up with shale naphtha and allowed to settle, water read off at 60° F.

Oil.—Scale which is poured off into a vessel immersed in a larger basin with water at 130° F. is allowed to cool slowly; maintained at 60° some time before weighing.

32grms. (500grs.) pressed five minutes at 60° F. between two discs of fine linen, with five circles of grey filtering paper on each side.

In conclusion, I have to render my thanks to those from whom I obtained note of various processes. To Dr. Wallace for liberty to mention the first; and last, but not least, to Mr. Boverton Redwood, by whose courtesy and letters I have been much encouraged in the hope that the object of my paper may be achieved.

As the opinions and suggestions contained in Mr. Redwood's letters are of importance, I beg permission to read them in full:—

85, GRACECHURCH STREET,
LONDON, E.C.,
26th January, 1887.

D. A. SUTHERLAND, ESQ.,
THE BURNTISLAND OIL CO., LIMITED,
BURNTISLAND

DEAR SIR,—I have carefully read the notes for your proposed paper, and am of opinion that the information you are in a position to convey will be of practical value, if only as showing the necessity for the adoption of some generally accepted method of operating.

(1.) As regards the *Determination of Water.*—The paraffin scale submitted to me is principally American. This scale usually contains less than 1 per cent. water, and I find that the method of assay which gives me the best results is to melt 25grms. in a tared hemispherical glass dish, and maintain it at a temperature of 230° F., with constant stirring (with the thermometer) until the weight is constant—the cessation of the crackling sound is a guide. When the quantity of water is considerable this method is tedious, and loss of scale by spurting *may* occur unless great care is exercised. In such cases I treat the scale with petroleum spirit and determine the water by measurement (in the way you describe), converting volume into weight in working out the percentage. It is important that the petroleum spirit used should previously have been caused to take up as much water as it will at the temperature of the experiment, otherwise there will be loss of water by solution in the spirit.

(2.) *Determination of Dirt.*—I prefer to get the dirt on a tared filter, where it can be washed with petroleum spirit (after the bulk of the scale has been removed by solution in the spirit).

Occasionally, however, it is more convenient to weigh the dirt in a tared dish or beaker.

(3.) *Determination of Oils.*—This stands upon a somewhat different footing, for it is necessarily a *purely arbitrary test*, the results depending entirely upon the manner in which the operation of testing is carried out—there being, of course, no natural or defined line of demarcation between the liquid and the semi-solid hydrocarbons present. I see you are acquainted with my method as described by me in the *Journal of Soc. Chem. Industry*. I do not know whether you have seen the further reference I made in my Cantor Lectures. I therefore send you a copy for perusal, in which, at pp. 56 and 57, you will find the remarks in question. These are chiefly interesting from what I previously stated in the Journal, that amount of pressure is of small importance compared with temperature.

I see you consider that the number of discs of absorbent paper should be specified, but would it not be equally necessary to specify the character (thickness, etc.) of the paper? It is my practice to employ so many papers that the outer ones are scarcely stained with oil, and I think you will find the results strictly comparative if this principle is carried out.

I note you have experienced difficulty in maintaining a temperature of 60° F. in pressing. You will find it a great advantage to adopt my present plan of having the plunger and cup of massive construction and detached from the bed-plate, etc., so that they can be cooled in water at 60°. They are provided with mercury cups and delicate thermometers.

---

* Messrs. Baird & Tatlock, 100 Sauchiehall Street, Glasgow, will supply these tubes.

There is no doubt that scale of a "doughy" character does not part with its oil with facility, but the process of slow cooling is now so generally adopted in refineries that it is comparatively rare to find scale marketed that is not fairly crystalline. I have had to write this letter very hurriedly, but I hope I have dealt with the points on which you wished for my views. I trust that your laudable efforts to place the subject upon a more satisfactory footing may be crowned with success.—Yours truly,
BOVERTON REDWOOD.

30th January, 1887.

DEAR SIR,—I am in receipt of your letter of yesterday's date, and enclose samples of the cloth and paper I use. These we cut with a steel die in the press, substituting the die and a hard wood block for the press-cup and plunger. Thus a considerable number can be cut of uniform size at one operation. You will find this method (perhaps you already adopt it) a great convenience. I do not think I have ever referred to it in print.

I forgot to say that the edge of the cup in which the scale is pressed is separate from the bottom, so that it can be lifted off. The "cake" is thus readily removed whole.

You are at liberty to make any use you like of the very hurried remarks contained in this and my previous letter.—Yours truly,
BOVERTON REDWOOD.

ADDENDUM.

Since reading the foregoing paper I have, by the kindness of Mr. Beilby, received a copy of an extract from the minutes of the Scottish Mineral Oil Association, dated August 13, 1884.

It consists of the report of an influential committee of oilworks managers who had been appointed to fully consider and discuss the subject. After unanimously recommending Mr. McCutchon's press, they gave the following recommendations :—

"1. That the quantity to be tested be 250 grains.

2. That the scale be freed from dirt and water by melting and settling, and the above-named quantity (250 grains) of the melted paraffin weighed and run into a mould, and thereafter cooled in water to 60° Fahr.

3. That the paraffin which is being tested remain under pressure for a period of 15 minutes.

4. That linen pressing cloths and a number of filter papers sufficient to absorb the oil (not less than six) be used.

5. That the maximum pressure be 10cwts. per square inch, and the working pressure 9cwts. per square inch."

Water and dirt estimation is not referred to. I am glad to be able to include these recommendations before the discussion, as they are a most valuable addition, being the result of no little investigation and discussion ; they are on the same lines as those laid down in the paper.

It is a matter of regret that the labours of the Association should not have resulted in the adoption of one standard commercial method.

It remains for all members of this widely representative Society interested in the subject to see that a final settlement is now arrived at.

DISCUSSION.

It was agreed to postpone the discussion on this paper.

◆

ON THE EMPLOYMENT OF "AGALITE" IN THE MANUFACTURE OF PAPER.

BY W. IVISON MACADAM, F.I.C., F.C.S.,
Professor of Chemistry, New Veterinary College, Edinburgh.

IT is well known that in the manufacture of paper there is frequently employed, besides the actual fibre, a quantity of material intended to weight the finished product, and, at the same time, enable the manufacturer to sell the article at a lower rate than would be otherwise possible were it necessary to send out only vegetable fibre.

For this "filling" or "weighting" many substances have been suggested and tried with more or less success. We may mention barytes or heavy spar or barium sulphate, stucco, kaolin or China clay, waste bleach (practically stucco), etc. Barytes being very heavy gives weight, but the great difference in specific gravity between the paper pulp and the barytes renders it very difficult to keep the bodies sufficiently mixed when the stuff is passing to the machine. Stucco and waste bleach are too coherent, and do not sufficiently intermingle with the pulp. With kaolin, which is the usually-employed substance, the difficulty arises that whilst the pulp and China clay are readily mixed, yet the substance is not retained sufficiently by the pulp, and passes into the effluent water, not only causing a loss of the China clay, but seriously aiding in the pollution of the waste waters, and therefore requiring to be removed from the liquids before these are allowed to pass into water courses. The above remarks would also apply to the effluent waters from works where cheap linen and cotton goods are finished and weighted.

The American printing and other papers are known for their beautiful surface and gloss, and many attempts have been made in this country to obtain a similar surface. The usual method of hot-pressing has not been found equal to the task, although much has been done in that way.

On examination of the ashes left on incinerating various portions of American paper, it is found that the loading material is of a fibrous character, and altogether different from the ashes obtained from the home-manufactured articles. The chemical analysis of the American paper ashes show them to consist of a silicate of magnesia, and the material used for loading is not, therefore, China clay, which is practically a silicate of alumina.

The material is a fibrous steatite found in large quantities in America. It is of a white colour, with a very slight tinge of green. It is somewhat readily reduced to a powder, the particles composing which are fibres. The specific gravity of the mineral is from 2·5 to 2·2, while the gravity of kaolin runs from 2·4 to 2·6.

The fibrous character of the agalite renders it possible to employ a larger gravity of the material with paper pulp than in the case of China clay, which, having no fibrous character, tends to weaken the manufactured article more than the agalite does.

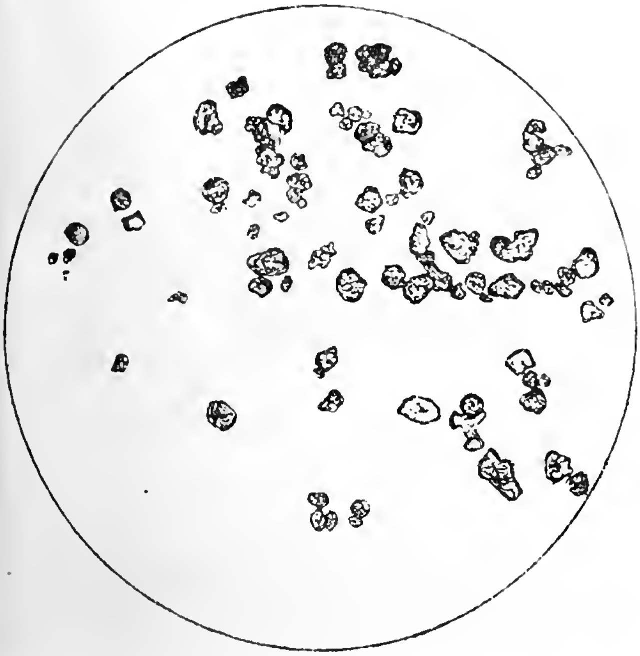
A series of experiments were made with linen rag pulp and the agalite, and with the same pulp mixed with China clay. The results are given below :—

Specific gravity of paper pulp (water 1000)	1012·94
Specific gravity of agalite	2·220 to 2·562
,, ,, of China clay	2·4 to 2·6

ANALYSIS OF PAPER PULP.

Water	96·58
Fibre	3·35
Ash	0·07
	100·00

A given quantity of pulp was placed upon metallic gauze of the size employed in the paper machine ; a second piece of gauze was then put over the pulp, the wires were surrounded by sheets of filter paper, and the whole transferred to the press. After fifteen minutes the materials were removed from the press, fresh blotting paper substituted in place of the now wet pieces, and the substance was again placed in the press. After ten minutes the material was removed,



CHINA CLAY.

Magnified 150 Diameters.

Magnified 150 Diameters.

AGALITE "A."

Magnified 150 Diameters.

AGALITE "B."

Magnified 150 Diameters.

the paper formed taken from between the wires and dried in the water oven till it ceased to lose weight. This process was repeated with the addition of 25 per cent. of China clay, with 25 per cent. of agalite, finer quality, and with 25 per cent. of coarser quality of agalite. The results obtained were :—

1. 1000 of paper pulp containing 33·5 grains of dry fibre yielded of dry paper 28·615 grains. In this experiment, made without the addition of any loading material, the actual loss of fibre was 4·885 grains per 1000, or 0·4885 per cent.

2. 1000 of paper pulp mixed with 25 per cent. (calculated on the dry fibre) of China clay yielded 38·170 grains of dry material, of which 32·9 was fibre and 5·27 clay. The theoretical quantities present in the materials experimented with were : Of dry fibre 33·5

grains, and of clay 13·2 grains. The loss sustained in converting the mixture into paper was equal to 0·51 grains of fibre and 7·93 grains of China clay, or to 0·051 per cent. of fibre and 63·6 per cent. of the clay used.

3. With 1000 of pulp and 25 per cent. of the finer ground agalite the results obtained were: Of dry material 45·63 grains, composed of 33·31 grains of fibre and 12·32 grains of the agalite, or an actual loss of fibre equal to 0·19 grains and of agalite 0·88 grains. These figures are equal to 0·019 per cent. of the pulp and 6·04 per cent. of the mineral used.

4. A test similar to No. 3, but made with a less finely ground sample of agalite, gave a total of 45·96 grains of dry substance, composed of 33·42 grains of paper fibre and 12·54 grains of mineral. The loss in this experiment was equal to 0·080 grains of fibre and 0·66 grains of agalite, or 0·008 per cent. of fibre and 5·28 per cent. of agalite.

These results therefore show that there is a decided advantage in substituting agalite for China clay, because not only is there an increase of dry paper, but such is obtained by a saving of fibre, as well as a decrease of the waste in the actual loading material, and a lessened amount of polluting matter to be dealt with. Moreover, the fibrous character of the agalite causes it to yield a paper of higher class quality than is the case with China clay. The extra gloss which it is possible to obtain with papers containing agalite is shown in various American journals and books.

The substance has been stated to be a silicate of magnesia, and to resemble asbestos in character. The actual results of the analysis of the mineral are given below:—

CHEMICAL COMPOSITION OF AGALITE AND KAOLIN.

	Agalite.
Silica	62·077
Magnesia	33·126
Water	4·286
Ferrous oxide	0·101
Aluminic	0·313
Undetermined and loss	0·094
	100·000

	Kaolin.	
Silica	61·02	49·65
Aluminic oxide	28·61	45·24
Ferric	1·96	0·31
Calcic	2·36	1·53
Magnesic	0·45	0·52
Potassic Sodic	1·76	0·78
Water and loss	3·81	1·91
	100·00	100·00

The samples which I have the honour of submitting to the Section have been kindly supplied by Messrs. A. B. Fleming & Co., Granton.

DISCUSSION.

Mr. Todd said that American paper had certainly a superior gloss, but that was the case, in his opinion, long before agalite was used, although Mr. Macadam was perfectly right in saying that agalite produced a fine skin. He pointed out, also, that in using vegetable fibre it was absolutely necessary to add China clay, as the paper would not print without it, and there were certain classes of paper, such as those used for printing with many colours, in which as high as 30 per cent. was used, as it was necessary to give it a genuine good dose, and while admitting that agalite was a very good thing, he knew the Americans produced the fine gloss on their paper from a different cause to that indicated by Mr. Macadam.

Mr. Macadam, in reply, said that it would be generally admitted that the Americans produced superior paper to ours, and in American Government contracts it was specially specified that azalite was to be employed because it gave a better gloss to the paper. He pointed out also, that if it was desirous to fill up the pores of the paper, he would do so by taking a fibrous rather than a non-fibrous material. Replying to a further question of Mr. Todd's as to what the loss would be on 100 grains of azalite if burned in a crucible, Mr. Macadam stated that the loss (which was practically water) would be 3·42 per cent.

◆◆◆

ON THE OCCURRENCE OF PETROLEUM IN A SHALE MINE AT BROXBURN.

BY D. R. STEUART, F.C.S., F.I.C.

Although the existence of petroleum in this country is by no means rare, with the exception of the so-called oil spring at Alfreton, in Derbyshire, utilised by the late Mr. Young and his partner, Mr. Meldrum, its occurrence has been considered more as a natural curiosity than of any practical importance or commercial value.

Sample Broxburn Petroleum.—In 1884 indications of the existence of petroleum were discovered at Broxburn (one of the centres of the shale oil trade of Scotland) when boring for shale to the north-east of that village. At about 100 fathoms the rods came up coated with petroleum of a semi-solid consistency. The sp. gr. of this oil was 0·842 and it assumed the consistency of butter (or it "set") at 75° F.

In the Sandhole pit, about 950 yards westward from the above-mentioned bore, petroleum was found in some quantity. This pit was sunk through the Broxburn and Dunnet shales to a depth of 10 fathoms below the latter; total depth, 155 fathoms—where a level mine was cut through strata which gave a constant ooze of oil and brine, while there was a strong odour of gas.

The sp. gr. of the petroleum obtained in this level is 0·830; the setting, or solidifying point, 61° F., and the colour is brown by transmitted, and green by reflected light.

Refined in the usual manner, it gave:—

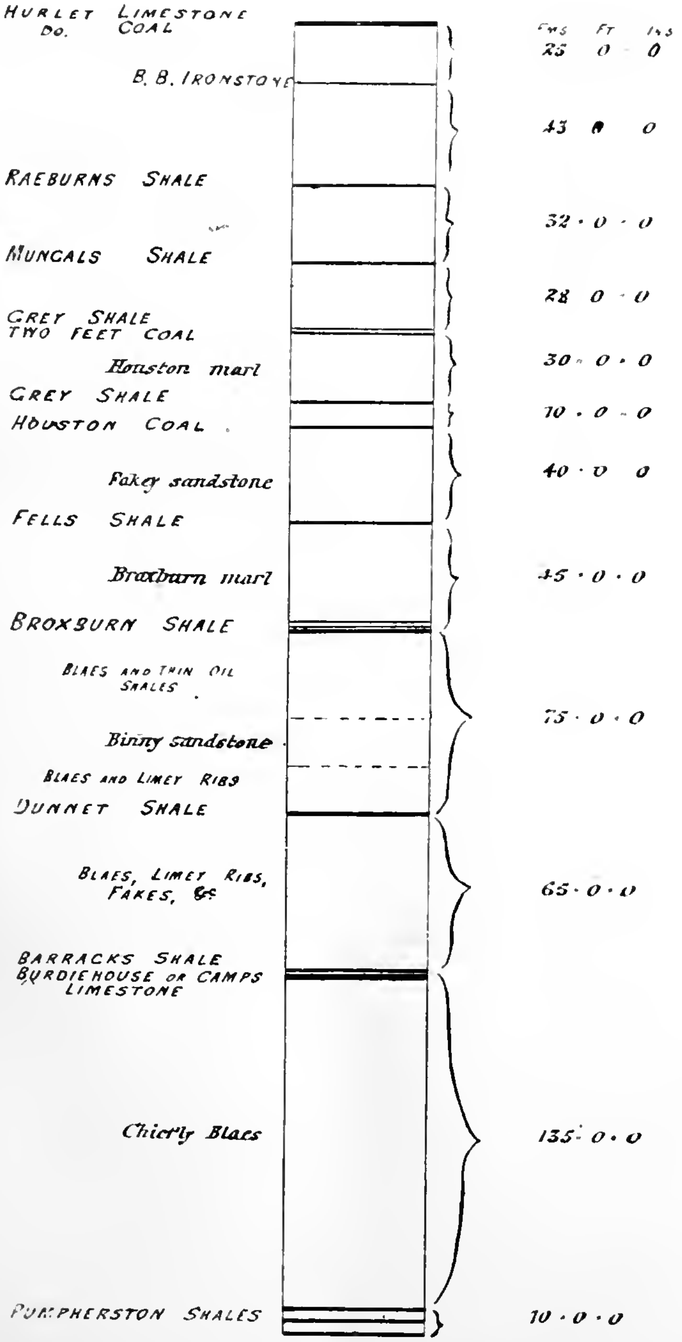
	Sp. Gr.	Per Cent.
Light naphtha	0·700	5·0
,,	0·730	5·2
Burning Oil	0·802	34·1
Intermediate Oil	0·840	10·5
Lubricating Oil	0·865	16·7
Paraffin Scale (melting pt. 103° F.)	—	12·5
Loss in refining	—	16·0
		100·0

The bromine-absorption, which indicates the proportion of olefines present, is much less than usual, as the following figures will show. Comparing refined burning oils, the bromine absorbed is: Baku, 0 per cent.; Broxburn petroleum, 6·5 per cent.; American petroleum, 11 per cent.; Broxburn shale oil, 40 per cent.

The brine which accompanies the petroleum has a sp. gr. of 1·095 (that of sea-water being 1·025) and gives 11,000 grains or 25oz. of solid matter in one imperial gallon, or 14·4 per cent. The salts present are chlorides of sodium, potassium, calcium, and magnesium, with traces of ferric chloride. Chloride of ammonium is present in amount equal to 0·01lb. per gallon.

In the Broxburn district combustible gas is given off from bore holes in considerable quantity. One at "Sandhole" blew about every minute. A bore hole at Middleton Gate (about a mile south-west), put down sixteen years ago, regularly, once a month, blew off gas for a day or two at a time. This intermittent discharge continued for many years. When lighted, the gas burned with a brilliant flame, about 20ft. in height, which was seen from a great distance. The discharge is now less frequent; occurring only at intervals of several months, and when the barometer is very low.

GENERAL SECTION OF THE BROXBURN DISTRICT



Of course the discharge of gas is a common enough thing from bore holes; but the association of brine, gas, and petroleum at Broxburn is of interest, as these are associated in other parts of the world.

The portion of the mineral field at Broxburn containing this natural petroleum is of considerable extent, and doubtless would yield sufficient oil to make it profitable to pump, if it would only flow. It, however, contains too much paraffin, and is semi-solid at a temperature below 61° F.; a simple, but fatal objection to this oil supply ever becoming of practical value or importance.

DISCUSSION.

The discussion on this paper was postponed owing to the absence of the author.

◆◆◆

EGYPTIAN PETROLEUM.

BY ROBERT IRVINE, F.C.S., F.R.S.E.

This oil, which is obtained both from superficial wells and deep bores, is found in the neighbourhood of Gemsah and Gebel el Zeit, a district in which crude oil has for some time been known to exist. The crude oil is of a dark brown colour, and has a disagreeable odour, owing to the presence of sulphur compounds, in this respect resembling the inferior qualities of Canadian and Italian petroleum. Its specific gravity is 0·934 at 60° F., and it is of a thick viscous nature, retaining its fluidity at low temperatures, owing to the almost entire absence of solid paraffin. Purified in the same manner as other natural oils, and those obtained by the distillation of coal and shale, it yields a product ranging in gravity from 0·850 to 0·950 (burning oil, such as is used for household purposes, being absent). On washing with sulphuric acid previous to distillation, the loss sustained exceeds 50 per cent., which is more than double the amount as compared with ordinary petroleum and shale oils. This loss, coupled with the expense of chemicals required for its purification, and the absence of burning oil (ordinarily so-called), puts it beyond the chance of being profitably purified; whilst, on the other hand, its heavy, viscous character, or body, and its non-liability to "set," give it a high place as a lubricant, as also make it suitable as a substitute for coal in steam-raising, in locomotive and other boilers. Gemsah, or Gebel el Zeit, is about 400 miles from Suez, on the western side of the Straits of Jubal, at the entrance to the Gulf of Suez; and this oil is said to be found in calcareous strata, in structure resembling coral. The amount of basic impurities present suggest that it is the product of decomposed animal matter.

Captain Roberts, from whom I obtained the oil, writes under date 24th January:—"The latest information I have is that one boring has reached 400ft., and at that depth coral, and, lastly, stiff clay, have been reached, and that they hope to find petroleum below this clay. About 50 casks of a very dark substance, called petroleum, were recently sent to Cairo. The crude oil is used successfully in lubricating the machinery of and in raising steam in a repairing establishment the Egyptian Government have at Suez. Two local steamers also use the crude petroleum for their engine bearings."

DISCUSSION.

Mr. Hamilton said he had also obtained a sample of Egyptian petroleum, but his results were somewhat different. The oil, of course, was very heavy, and totally unsuitable for use as a burning oil; on the other hand, the lubricating oil was the most magnificent he had ever seen for what was known as viscosity and lubricating purposes, while the loss in treatment was very little.

Mr. Harris: What was the proportion of the 0·930 lubricating oil in the Egyptian oil?

Mr. Hamilton: 45 to 50 per cent.

Mr. Laing said that he had received from the Egyptian Government two gallons of petroleum, both of which he distilled with steam and without steam. He got a considerable percentage of lubricating oil—about 70 per cent. in both cases—although the sample distilled with steam purified more readily than that distilled without it.

◆◆◆

ADJUSTABLE THERMOMETERS.

BY ANDREW HADDOW.

All users of thermometers may not be aware that these instruments undergo a gradual change for some time after their manufacture, and that although possibly quite correct when they left the makers' hands, they may indicate a much higher temperature than what is correct in a year or two, the increment of change being less as the thermometer becomes older.

This change of zero was first noted by M. Flaugergues in 1822.*

Dr. Joule found the change going on during twenty-six years.†

Despretz tested the rise during five years, the curve formed being sensibly a parabola.‡

The writer has found the rise of zero in thermometers from two to five years old to be from 2 to 2½ degrees.

The rise of zero appears to be due entirely to molecular changes in the glass, because it goes on even when the tube is not sealed, and, consequently, when there is no greater pressure outside than inside.

A method for hastening the change of zero, by keeping the thermometer tubes at a high temperature for some time before graduating, is described in the *American Chem. Jour.* for 1884.§ Besides this permanent rise of zero, there are temporary rises and falls due to immersing the thermometer in very cold or very hot liquids.‖ These temporary errors disappear in from ten to fourteen days.¶

In some operations—for instance, in the manufacture of ice—2½° would represent 50 per cent. of the whole power of the machine, while in brewing operations (where really good beers are brewed) every fraction of a degree has an important influence on the final product. Standard thermometers from Kew Observatory may be used, but these are very costly, easily broken and difficult to read, the figures being on a glass tube instead of on a separate scale.

In practice it is usual to make allowance for the error of the thermometer, but this is a very dangerous practice from the liability to make the allowance on the wrong side, thus doubling the error. For instance, a workman is told to cool down a liquid to 60°, and he learns that his thermometer reads a degree too high; he then makes up his mind that he will read the thermometer a degree lower than 60°, the result being that he cools the liquid 2° too low—namely, to 58°.

The only way that can be depended on for accurate work is to use practically correct thermometers, or in some operations, thermometers which at least all agree with one another. A thermometer which can be adjusted for error fulfils all that is required in practice, and the writer has patented the construction of thermometers in which the tube is fastened at one end to a separate piece, sliding in the

¶ Balfour Stewart's "Treatise on Heat," p. 15 (1866).

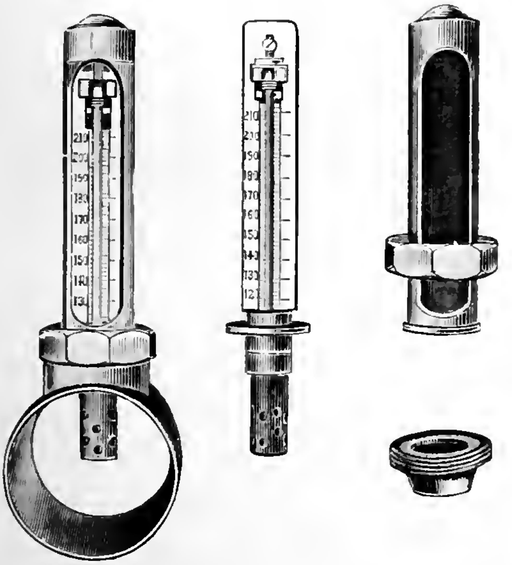
scale, by means of which any user of thermometers can at once adjust them to agree with a standard, or with one another.

In the manufacture of these thermometers, tubes must be rejected when the difference in length between 10° at one part of the scale and 10° at another part of the scale, is more than half a degree. With this amount of difference, and a rise of zero equal to 2°, the adjustment allows of the greatest error at the extreme ends of the scale being reduced to one twentieth of a degree, which error gradually diminishes until it vanishes at the centre of the scale. This amount of error is of course quite inappreciable in manufacturers' thermometers.

For scientific work the tubes must be more carefully selected, and as old as possible.

The patent pipe thermometers remove several inconveniences felt by users of this class of thermometers.

In the prevailing design there is an internally screwed socket soldered into the pipe, the contents of which it is desired to test, and the thermometer has a screw formed on it which should fit the socket, but it often happens, when a new thermometer has to be screwed into an old socket, that the two do not fit, also when one of these thermometers is screwed in tight it may be facing in the opposite direction to what is desired, if slackened back leakage occurs, and if tightened up further the case is liable to be broken, or the screw overhauled.



In my patent thermometer these two difficulties are overcome by attaching the thermometer to the socket by means of a flange instead of a screw. The screwed socket and the nut form a part of the case, and remain together when the thermometer is removed. The flange allows the thermometer to be set facing in any desired direction, and tightened in that position to any desired degree. The other improvements refer to strengthening the case, and lessening the chance of leakage past the glass tube.

Professor Crum Brown, in moving a vote of thanks to the authors of the papers, hoped that the success which had attended the first meeting of the Section in Edinburgh would induce them to renew the experiment before long, and would increase the membership and the interest of members in the work of the Society.

On the motion of Mr. Stanford, a very hearty vote of thanks was awarded to the Chairman for his kindness in placing the rooms of the new Chemical Laboratories of Edinburgh University at the disposal of the Section.

CHROMIUM MORDANTS.

BY R. LLOYD WHITELEY, F.C.S.,

Lecturer on Dyeing, etc., University College, Nottingham.

Chromium was first discovered by Vauquelin in the year 1797, but bichromate of potash does not appear to have been used as a mordant for cotton till 1820, by Koechlin, nor as a wool mordant till about 1840, whilst it was not introduced into this neighbourhood (at Loughborough) till 1850.

Bichromate of potash, or "bi-chrome," is not only used for its own sake as a mordant, but also as the starting point for many other chromium compounds. It is, perhaps, hardly necessary to mention the fact that chromium can play the part of an acidulous as well as a basilous radical. "Bi-chrome" is an example of the former, and in thinking about its use as a mordant, I was led to try to throw some light on its action, more particularly in wool dyeing; viz., to ascertain whether at the end of the mordanting operation it were still present as "bi-chrome," as chromic hydrate, or in some intermediate stage of oxidation. At the same time I wished to ascertain the influence of temperature, both on the mordanting and dyeing processes, as well as to notice the effect of different states of dilution.

A very general idea has been that when wool was boiled with "bi-chrome" only, a deposition of chromic hydrate took place upon the fibre; but the wool mordanted in this manner does not appear green, as it would do if there were green hydrated oxide deposited. That being so, the most natural explanation is that the chromate simply soaks into the body of the fibre. That this is so is shown by sulphurous acid giving to a mordanted pattern a *green* colour. The wool used had been mordanted in a strong "bi-chrome" bath, being put in cold and heated up to the boil, the total time of immersion being an hour-and-a-half. It was then carefully washed with distilled water till the wash-waters gave no trace of chromic acid, so that the greenish hue produced by the reduction could not be merely a surface colouration. A portion of this wool was also taken and immersed in a solution of silver nitrate, and after a little standing a reddish brown colouration of the wool took place, which was, no doubt, due to the formation of silver chromate. After this the remainder of the wool was allowed to stand in distilled water for a week, and at the end of that time the water showed distinctly the presence of a chromate, which had evidently diffused into it from the wool fibre. The wool itself could still be turned brown by silver nitrate, as well as give a decided yellow with a solution of lead acetate and acetic acid. It was, therefore, once again washed till the washwater showed no traces of chromate, and it was once more allowed to remain in water for a week. At the end of this time the liquor and wool were again examined, with the result that chromic acid was found in both; but, after rewashing at the end of another week, the wool retained its power of dyeing yellow in lead acetate, whilst the diffusion back of the chromate, with the liquor, seemed to have ended.

Besides these tests showing the presence of a chromate in the wool, the original liquor was carefully tested for chromium in the state of a chromic salt, but not the slightest trace could be detected. This experiment was performed with an exceptionally large amount of "bichrome" in the bath, so as to obtain, if possible, a clear result. These results seem to show, that when wool is mordanted with bichrome alone, *no reduction* takes place. In order to confirm this the experiment was repeated and another was carried out with acid in the bath. It was found that when acid was absent, both the liquor and mordanted pattern gave the same re-actions as in the previous trial; whilst in the other case, in which sulphuric acid was used in the bath in the proportion of 1 molecule of acid to 1 molecule of bichrome, a mordanted pattern was obtained, which bore a distinct green tinge, the liquor gave a precipitate with dilute ammonia, and also showed the presence of unchanged chromate. It is, therefore, evident that in this case we have both acid and hydroxide on the fibre. I noticed, too, that the pattern mordanted with bichrome only was much more easily washed free from reagent externally than the other, as if in the latter case the action had been such as to render it more sponge-like in texture, or else to thoroughly loosen the imbrications of the fibres by the oxidation of adhering fat. After this I planned a somewhat lengthy series of experiments, with the view of trying the influence of different temperatures on the mordanting operation, both when the bichrome was used alone, and also when assisted by sulphuric acid. I also intended to analyse the liquids, so as to ascertain the change which had taken place in their composition. The part relating to chrome alone I carried out as far as testing the influence of temperature, but I shall have to adopt different apparatus in which to mordant so as to obtain accurate comparative analytical results, though with the apparatus used the analytical results would seem to show that it is a question of absorption unchanged into the fibre.

To easily obtain accurate comparative results as to the amount of chromic acid remaining, it will be necessary to use a liquor of accurately known strength for mordanting, and perform the operation in a vessel provided with an inverted condenser. With regard to temperature you will see that the trials have yielded some interesting and instructive results.

I took six sets of six patterns each. In each set every pattern was numbered with the same number. These sets were mordanted in a liquid which contained bichrome in the relation of 3 per cent. of their weight; the sets were all entered cold and heated up to 50°, 60°, 70°, 80°, 90° and 100° C. respectively as quickly as possible, and mordanted for a total period of an hour-and-a-half. These sets, after being washed, were redistributed into six new sets, in such a fashion that each pattern in each set was mordanted at a different temperature, and these sets in their turn were dyed in a bath of logwood liquor, at the temperatures 50°, 60°, 70°, 80°, 90° and 100° C. respectively. The results, when arranged in order, show a distinct convergence of colour towards the pattern which was both mordanted and dyed at the boiling point. In every case the pattern mordanted at the highest temperature gives the best result.

This is an important result, since it shows that a dyer does not get his best result (in the case of logwood) unless he both mordants and dyes at the boil, and that in any case mordanting at the boil gives the best result with "bi-chrome." It was also noticed that no dyeing action took place till about 40—50° C. The corresponding trials with acid in the bath I have not yet been able to carry out.

Coming next to the question of dilution. Does a greater or less amount of dilution affect the final result, or is it merely a question of the actual amount of salt in the bath? Siebold (this Journal, 266, 1885) says that it practically does not matter about dilution, the ratio between wool and mordant being the main point. I have not carried out his experiments afresh, but those I have made go to prove that both the increase and decrease of strength have an effect similar to that of the use of larger or smaller quantities of the chromate; and if the wool possesses little or no preferential affinity for the bichromate this is what might be expected.

When we come to the use of bi-chrome and acid together, this fact is still more strikingly shown, and it is easy by mere concentration to overchrome the pattern. For instance, whilst 10grms. of wool mordanted with 3 per cent. of its weight of bichromate, and 1 per cent. of sulphuric acid in 1200cc. of water, gives a good colour, the same amount of mordant in 600cc. produces an overchromed pattern. These results were obtained under strictly comparable conditions.

The practical bearing of these experiments is therefore to emphasise the influence of temperature on dyeing results, and also to show that dilution *does* require to be taken into account in determining the percentage of mordant to be used.

What, then, is the best way of using "bi-chrome"? Experiment has shown that about 3 per cent. of the salt (compared with the weight of the wool) is sufficient, under ordinary circumstances, to give a good blue-black; but the addition of 1 per cent. of strong sulphuric acid improves the result; the reaction which occurs probably being represented by the following equation:—$K_2Cr_2O_7 + H_2SO_4 = K_2SO_4 + 2H_2CrO_4$, since the proportions used are such as to satisfy its requirements.

It must be noted that this proportion of acid does not always hold good; many circumstances will affect it—*e.g.*, very hard water; or, again, whilst it might be perfectly right for logwood, it very possibly might not be suitable to its extract. The presence of easily reducible substances in the extract may even do away with the necessity of adding sulphuric acid; in fact, may make its presence an evil. You will, therefore, see that the practice of every dyer should be governed by his special conditions, which may be carefully ascertained by experiment, and worked from accordingly. Besides sulphuric acid, tartar is employed so as to bring about similar results. Its action is questionable. It may act by neutralising the potash and liberating chromic acid; but, probably, whether it does so or not, it also acts the part of a reducing agent, and so helps the precipitation of the hydrate on the fibre. This idea is supported by the fact that it gives bluer shades than those produced by H_2SO_4, and also by the known fact that oxalic, tartaric and citric acids all convert soluble chromates into green solutions of chromium salts with evolution of CO_2, and that alcohol and sugar in presence of an acid will also do the same (Gmelin). It becomes then a question whether the expensive tartar may not be replaced by cheaper materials, such as treacle, glucose, etc., and so obtain like results at a much cheaper rate.

For certain classes of blacks the addition of a small amount of copperas to the bath gives a very good result; it has the effect of slightly reddening the black, and probably will counteract the tendency which chrome blacks have of turning green; but in the hosiery trade such a black is of no use. Copper sulphate, on the other hand, has almost the opposite effect; and it is possible that about a quarter per cent. of each would produce a black which would not show such greening tendencies.

Turning next to the use of chromium salts. These, more especially chrome alum, if used at all, do not find a very extended use in the wool-dyeing industry. Neither the alum nor the sulphate yield the hydrated oxide in sufficient quantity to produce deep shades. The ease with which the bichromate can be used, will stand in the way of any development of their use on wool, especially as, in the case of the chrome and acid, there is little doubt that the result is due to two actions—viz. (1) the hæmateïn forms a lake with the precipitated chromic hydrate; (2) the free or combined chromic acid oxidises the hæmatoxylin, and then combines, after its reduction, with the hæmateïn thus produced. When we turn to its use in cotton dyeing, we meet at once with a very different set of conditions. Cellulose, unlike wool, is a comparatively inert substance. Whilst in the case of wool the chromic acid is reduced, either at the expense of the fibre itself or of unremoved fats, in the case of cotton comparatively little action would take place, except such as led to the disintegration of the fibre; besides which, cotton does not possess so great an amount of elective affinity or absorbing power as wool does. The principal use of this salt is, therefore, rather to serve as an oxidising agent or for the formation of other chromium compounds, than as an actual mordant for cotton; *e.g.*, in cutch dyeing, the cotton, after steeping in the cutch, is passed into a hot bath of bichromate, to oxidise the cutch, and to produce the so-called japonic acid. A considerable quantity of chromic hydrate is deposited on the fibre at the same time, and no doubt influences the shade, but whether merely by its own colour or as a mordant, is perhaps questionable, though it will act as a mordant for other colouring matters. To form chromic salts, such as nitrate, acetate and aceto-nitrate, etc., bichrome is, however, largely used; these salts are formed by the reduction of the bichromate in presence of a suitable acid, by some such reducing agent as glucose, glycerine, alcohol, etc. The object in producing these bodies is to obtain a chromium salt of such a nature that it easily yields its oxide to the fabric, and the more basic it is the more easily will it dissociate on dilution, or heating, or both. The great obstacle to the extended use of chromium salts in dyeing cotton, has been the difficulty of fixing a sufficient quantity of the mordant to produce good shades; they have, however, been considerably used by calico printers, being fixed by steaming. For dyeing purposes, various processes of precipitation have been proposed, and one of the latest and most successful consists in steeping the cotton in some chromium solution, drying, and then passing it through a solution of carbonate of soda. The other methods have not been satisfactory.

More recently, Koechlin (this Journal, *1885*, 115) recommends a mordant prepared by adding excess of caustic soda to chromic acetate, the goods being passed through this and then thoroughly washed in running water. Schmid has modified this so as to obtain it more cheaply, but there is still the difficulty of working in such alkaline solutions, which will no doubt prevent its general adoption. Mons. E. Blondel (Abst. *Dyers and Colourists' Jour.*, Dec., 1886) suggests the employment of a basic double nitrate of chromium and calcium, which is easily dissociated when sufficiently dilute. Whether this can be used in the cotton-dyeing trade here is a question for someone practical to settle; but it presents interest because of the presence of the earthy metal in it, and we know that in certain cases—*e.g.*, in alizarin dyeing, there is produced on the fibre a lake containing lime in its composition.

In concluding I would draw your attention to some very interesting work of Liechti and Suida, of which an abstract is given in this Journal (*1885*, 586—590), and which is well worthy of the attention of all practical men.

Journal and Patent* Literature.

I.—GENERAL PLANT, APPARATUS, AND MACHINERY.

Improved Means of preventing Incrustation of certain Parts of Steam Boilers. S. Fox, Leeds. Eng. Pat. 2376, Feb. 18, 1886. 8d.

This is an appliance for keeping the upper surfaces of horizontal cylindrical fire-boxes and flues of boilers clear from deposit, by the use of scrapers fixed to chains which are laid across the flues, their ends held down by weights. The chains are occasionally moved over the flue from one side to the other by suitable gearing, for the purpose of scraping off and preventing any accumulation of deposit.—B.

Improved Apparatus for indicating or regulating Temperature, Pressure or Volume of confined Fluids. J. Thomson, Glasgow. Eng. Pat. 2520, Feb. 20, 1886. 8d.

This is a development of a previous patent (J. Murrie, Eng. Pat. 303, 1885), in which use is made of a hollow chamber inserted in the enlarged part of a tube which is connected to both the liquid and vapour spaces of a vapour generator. The hollow chamber is fixed at the height of the ordinary level of the liquid in the generator, and as its immersion varies with changes in the level of the liquid, it receives more or less heat, whereby the tension of the enclosed air is altered and noted on an outside dial. From this indication the change in the level of the liquid may be deduced, and the same principle can also be applied to other purposes, several of which are referred to.—B.

An Improvement in Glass Hydrometers. S. A. Calderara and A. J. Calderara, London. Eng. Pat. 3594, March 13, 1886. 8d.

This refers to the manufacture of glass bulbs of hydrometers by blowing them in moulds with the view to the production of any desired shape or size of bulbs.—B.

Improvements in Filtering Funnels. W. C. Nickels, London. Eng. Pat. 8375, June 25, 1886. 8d.

THE improvement consists in making filtering funnels double, with a space between the two cones, the inner one, on which the paper rests, being perforated with small holes, so as to allow free escape of the liquid all over. A slight vacuum may also be maintained in the space between the two cones by artificial means, which greatly accelerates the filtering process, without injury to the paper.—B.

II.—FUEL, GAS, AND LIGHT.

Professor Seger's Pyroscope and Observations on the Temperature in the Interior of Gas Retorts. A. Heintz. Journ. f. Gas. u. Wasservers. **29**, 894.

FOR description of the applications of the above instrument, see this Journal, 1886, 489–491.

Improvements relating to the Purification of Illuminating Gas and other Fluids, and to Apparatus therefor. F. Lux, Ludwigshafen, Bavaria. Eng. Pat. 15,478, Nov. 26, 1886. 8d.

THIS invention is based upon the principle of alternately contracting and expanding the gaseous current, and is carried out by dividing the said current into several streams and passing these through series of chambers (preferably contiguous to one another), the enclosing walls of which, being convoluted, continually change the sectional area in the direction of the current. It is claimed that the sudden changes of velocity produced in the gaseous current by this alternate expansion and contraction of its channel cause a most complete deposition of the mechanically carried solid or liquid matters. This deposition may be aided by the insertion of baffle plates where the channel is widest.—A. R. D.

Improvements in the Manufacture, Blending, or Treatment of certain Mineral Hydrocarbons or Compounds of Hydrocarbons. S. Banner, Liverpool. Eng. Pat. 603, January 14, 1886. 6d.

THIS invention consists in adding any one or more hydrocarbons of one chemical series, say the paraffins, to any one or more of the nearly corresponding hydrocarbons of another series, say the olefines. The specific gravity of the mixture thus produced is higher than the mean of those of the separate liquids, and there is a corresponding improvement in the index of viscosity and the flashing point.—A. R. D.

Improvements in Incandescence Gas Lights. F. L. Rawson, and T. V. Hughes, London. Eng. Pat. 1195, Jan. 26, 1886. 8d.

THE improvements consist in maintaining a constant relation between the area of the incandescent material and the amount of gas, or gas and air, used in the burner. This may be done by so connecting the incandescent envelope with the tap controlling the gas supply that the envelope and burner are moved relatively to one another as desired. The waste heat is used to warm the air required for the burner.—A. R. D.

Improvements in Incandescence Gas Lights. C. von Buch, London. Eng. Pat. 1235, Jan. 27, 1886. 8d.

THE inventor uses a framework of platinum wire to support the material that is to be made incandescent. In the case of woven or fibrous material the wire is introduced into the texture at suitable intervals, the lower rim of the frame, or projections therefrom, being conveniently attached to the mouth of the burner.
—A. R. D.

Improvements in Apparatus for the Manufacture of Artificial Fuel. S. W. Allen and G. Breflit, Cardiff. Eng. Pat. 2807, Feb. 26, 1886. 8d.

THIS invention relates to the desiccation of the materials used in the manufacture of the fuel. The desiccating apparatus is surmounted by a vertical steam pugg, the central revolving shaft of which is continued downwards and carries a series of bottomless saucers or annular plates. Each saucer (except the top one) has a smaller inverted saucer interposed between it and the larger saucer next above. The hot gases from some furnace of convenient construction are made to ascend through the desiccator, thus drying the fuel on the saucers. In operation the raw material is treated in the pugg and let down through regulated openings on to the topmost saucer, whence it is scraped by proper scrapers, so as to fall over the intermediate saucer (which thus acts as a spreader) on to the larger saucer next below. Falling thus from saucer to saucer in zig-zag course, the material may be desiccated to any desired degree.—A. R. D.

Improvements in Gas Producers. F. Radcliffe, Plumstead. Eng. Pat. 7377, June 2, 1886. 6d.

THE inventor supplies the producer with fuel from below by means of a hydraulic ram or screw. The ram works in a charging-box connected with the bottom of the producer, and this box is filled from a spout or hopper. Before the ram begins its upward stroke the filling aperture of the box is closed with a slide. When a charge has been forced into the producer, and the ram is about to descend, the fuel is prevented from following by an iron plate which was laid loosely on the ram-table before the charging-box was filled, and is now caught by two horizontal bars (which are passed through holes in the casing) and held till the box is filled again and the ram ready to begin its upward stroke. The plate is then drawn out by a suitable slot, and all is ready for the insertion of another charge.—A. R. D.

Improvements in Apparatus for Distilling or Refining Mineral Oils. R. Tervet, Musselburgh, N.B. Eng. Pat. 8494, June 29, 1886. 8d.

THIS apparatus consists of a horizontal cylindrical vessel divided by vertical partitions into a number of compartments corresponding to the number of stages of the distillations to which the oil is to be subjected. To take one modification for example, the cylinder is divided into five compartments, and the oil is fed into the central one for the first stage. After this it passes, by any suitable connections, to the two adjacent compartments for the second stage, and from these to the two outer or end compartments for the third stage. From these it is transferred to ordinary coking-stills. The transference of the oil from compartment to compartment may be either continuous or periodical, and may be accomplished by gravitation only or by the aid of steam pressure. The graduation of the heat employed in the distilling process may be attained by placing the fires under the end compartments and using the fire gases first to heat the intermediate compartments and then the central one. Or a separate fire may be placed to each compartment and regulated as required.—A. R. D.

An Improved Method and Apparatus for rendering a Liquid Hydrocarbon Gaseous. Jas. Roots, London. Eng. Pat. 13,967, August 16, 1886. 8d.

A CYLINDER, having a tightly-fitting piston, is provided with an inlet and an outlet valve. Air and benzoline in suitable proportions are drawn into the cylinder by one stroke of the piston, and, by the next, are forced out again into and through a vessel packed with fine wire gauze, asbestos, cotton, or the like. This packing ensures the fine division of the hydrocarbon, and so materially aids in impregnating the air with the vapours thereof. Other hydrocarbons besides benzoline may be used. With the heavier ones the aid of heat is required.
—A. R. D.

Improvements in the Purification of Coal-Gas and in Apparatus therefor, the same being in part applicable for the Preparation of Caustic Ammonia Solutions. W. Young, Peebles. Eng. Pat. 16,052, Sept. 29, 1886. 1s. 3d.

THIS is an improvement on the known processes for using gas liquor to purify coal-gas. By these, as hitherto conducted, gas liquor is freed from its carbonic acid and sulphuretted hydrogen by being raised to a temperature somewhat below 100° C. The remaining caustic ammonia solution is used to absorb the acid gases from a fresh portion of coal-gas by being passed through a scrubber in a direction opposite to the flow of the gas. The chief objections to these processes are that at ordinary pressure the temperature that is required to drive off the carbonic acid and sulphuretted hydrogen is very apt to drive off the ammonia also, and that the ammonia solution entering the scrubber and meeting the comparatively pure gas leaving the same, is also very apt to part with ammonia, which goes forward with the gas and has to be scrubbed out again with water. The patentee obviates these difficulties by conducting the operation under a pressure of from 30 to 50lb. This pressure raises the solubility of the ammonia far more than that of the carbonic acid and sulphuretted hydrogen, and so enables much stronger gas liquor to be dealt with. In the subsequent operation the caustic ammonia solution is caused to pass through the scrubber in the same direction as the gas. By this means the strongest ammonia liquor is brought into contact with the crudest gas, and the less volatile carbonates and sulphides formed at once. For particulars of the elaborate apparatus with which the patentee carries out his invention, the specification with its drawings must be consulted.—A. R. D.

An Improvement in the Purification of Coal-Gas. H. Bowater, Cradley. Eng. Pat. 2892, Nov. 2, 1886. 4d.

THE gas is passed through a heated passage, and the higher the temperature to which it is raised the more perfect is the realisation of the advantages claimed. These are chiefly: That inferior coal can be made to yield gas of the best quality; that the hydraulic purification may be dispensed with; and that all noxious smells are destroyed.—A. R. D.

III.—DESTRUCTIVE DISTILLATION, TAR PRODUCTS, Etc.

On Russian Bakuols. J. Jlimow. Chem. Zeit. **10**, 1459—1460.

MENDELEJEFF gave the name of bakuol to a product of distillation of the Caucasian petroleum, which had the specific gravity of 0·820 to 0·900, and represented a mixture of several fractions. More than 50 per cent. of bakuol can be obtained from the crude oil of Baku, whereas the yield of kerosene, which is usually employed for illuminating purposes, does not exceed 30 per cent. For determining the illuminating power of bakuol, different kinds were burned in a common German lamp, and their lighting effect was measured by a Bunsen photometer. At the same time commercial kerosenes were examined under precisely the same conditions, and it was found that the bakuols were decidedly preferable to kerosenes as illuminating agents. The following table contains the results of the experiments :—

No.	SPECIMEN OF OIL.	Specific Gravity at 17·5° C.	Flashing Point at 760mm.	Illuminating Effect in Candle-units.	Consumption of Oil in Russian Pounds per Hour.	
					For the Lamp.	For Candle-units.
1	Oil Fine (Nobel)	0·8218	29·5	9·00	0·0667	0·0074
2	,, ,,	0·8268	32·0	8·65	0·0720	0·0083
3	,, ,,	0·8200	27·0	9·20	0·0670	0·0073
4	Kerosene (Schibajew)	0·8225	27·0	8·01	0·0662	0·0077
5	,, (Mirzojew)	0·8125	32·0	7·85	0·0690	0·0088
6	,, (Ropes)	0·8188	35·0	9·25	0·0650	0·0070
	Astrolin	0·8108	57·0	8·20	0·0687	0·0083
8	Pyronaphtha (Kordig)	0·8157	47·0	7·70	0·0658	0·0085
9	,, (Ragosin)	0·8508	73·0	7·30	0·0610	0·0083
10	Bakuol No. 1	0·8280	36·0	7·40	0·0588	0·0080
11	,, No. 2	0·8310	37·5	10·10	0·0633	0·0060
12	,, No. 3	0·8360	39·5	9·84	0·0633	0·0061
13	,, No. 4	0·8310	49·5	8·30	0·0675	0·0081

The table on next page contains the fractions, with their specific gravities, of four different kinds of kerosenes and bakuols.

Considering the great illuminating power, combined with the high-flashing test of the bakuols, and principally the greater yield of bakuol to be obtained from crude oil, the author expresses the hope that petroleum distillers will find it more profitable to manufacture bakuol from Caucasian petroleum, than to distil the latter for kerosene after the American fashion.—S. H.

On Pyrene. E. Bamberger and M. Philip. Ber. **19**, 3036—3040.

IN a previous communication (this Journal, 1886, 595) it was shown that by the oxidation of pyrenic acid, naphthalenetetracarboxylic acid $C_{14}H_8O_8$ is obtained. In treating a large quantity of this acid, a second oxidation product is obtained, forming long orange needles with a vitreous lustre melting at 191°. Owing to the want of material, however, the investigation of this substance could not be pursued. When *naphthalenetetracarboxylic acid* is gradually heated to 150—170°, two molecules of water are liberated with formation or *naphthalenetetracarboxylic dianhydride* $C_{10}H_4(CO.O.CO)_2$. This substance crystallises from glacial acetic acid in white lustrous needles. Naphthalenetetracarboxylic acid therefore contains two pairs of carboxyl groups in ortho-position, a circumstance which receives confirmation by the formation of *naphthalenetetracarboxylic diimide* $C_{10}H_4(CO.NH.CO)_2$ from the dianhydride by treatment with ammonia. On oxidising pyrene ketone $C_{15}H_8O$, prepared by distilling pyrenic acid with lime, a dibasic acid $C_{10}H_6(COOH)_2$ is obtained which is decomposed into naphthalene and carbonic anhydride when distilled with lime. This acid melts at 265°, yields a characteristic imide, and appears to be idenfical with the naphthalic acid obtained by Behr and Van Dorp from acenaphthene. By determining the position of the acid groups in naphthalic acid the authors expect to decide the constitution of pyrene.

—D. B

Improvements in the Manufacture of Coke for Metallurgical Purposes. H. Barclay and R. Simpson, Harrington Iron Works, Cumberland. Eng. Pat. 2307, Oct. 28, 1886. 6d.

THE coal to be coked is put through a suitable disintegrator and mixed with 4 or 5 per cent. of slaked lime in fine powder. The coke produced is less friable and more compact in structure than that made in the ordinary way. This invention is only applicable to ovens of the Bee-hive type.—A. R. D.

IV.—COLOURING MATTERS AND DYES.

The Manufacture of Methylene Blue. Otto Mühlhäuser. Dingl. Polyt. J. **262**, 371—379.

THE two processes in use for the manufacture of methylene blue are based upon two reactions, the one discovered by Caro in 1876 being the oxidation of dimethylparaphenylenediamine in acid solution in the presence of hydrogen sulphide; the other, described by Oehler in 1882, being the oxidation of a base containing sulphur, and which is obtained by treating a strong sulphuric acid solution of nitrosodimethylaniline with sulphuretted hydrogen.

PROCESS WITH "SODA WASTE."

The apparatus for the raw colour consists of two series of three wooden vats, the upper one provided with cover with manhole, stirrers, and draught connected with the flue for the removal of gases; also two sets of three filter boxes. For the purification, there are two vats for the extraction and two for the precipitation of the colours, and the requisite filters. The vats each hold about 3000 litres (660 gallons).

Nitrosodimethylaniline Solution.—Into each vat 1200 litres of water are run and a mixture of dimethylaniline hydrochloride added. This mixture is made by diluting a carboy of hydrochloric acid with 50 litres of water in an enamel pan, and well stirring into this 10kilos. dimethylaniline. Each vat is also provided with a vessel with run-off cock in which 6·6kilos. nitrite of soda are dissolved in about 150 litres of water. The temperature of the solution in the vats is regulated by ice or steam to about 8—9° C., and then, whilst well stirring, the nitrite gently run in through lead funnels which reach to the bottom of the vat. This requires about two hours, after which two carboys of hydrochloric acid are added to each vessel.

Reduction and Saturation with Hydrogen Sulphide.—Fresh, moist, "soda waste" supplies the latter, and can be measured conveniently in a wooden pail to hold about 35kilos. "waste." Two such pails of "waste" are required to expel excess of nitrous acid from all three vats; ⅓ pail is added at a time to each vat, whilst stirring well. Thereupon two more carboys hydrochloric acid are added to each batch, and a pailful of "waste" thrown in, and then the stirrers thrown out of gear so that the evolution of gas can take place slowly and regularly. With panses of 1½ to 2 hours, 4 to 5 pails altogether of "waste" are added, and the reduction is then complete, a drop of the solution on filter paper no longer showing the yellow nitroso-edge. During this operation the colour of the liquor changes from yellow, through dark green, brown, black, blue, and red to a milky white, and the temperature rises about 5°—viz., from 16° to 21°.

The Oxidation.—For this purpose a solution of ferric chloride of 1·16 to 1·17 sp. gr., containing 20—21 per cent. Fe_2Cl_6, is added in slight excess to the solution in the vats. The odour of H_2S must then entirely have disappeared, and the liquid must appear deep blue, also the clear solution from a sample precipitated with salt and zinc chloride should give a slight blue colouration with ferrocyanide of potassium. The colour thus formed is then salted out with 180kilos. rough salt and about 25kilos. of zinc chloride solution, containing 44 to 49 per cent. $ZnCl_2$ (1·5 sp. gr.). A drop on filter paper must show blue flakes on a *red* ground. The filtration is then proceeded with, stirring constantly, and takes two or three hours. The raw colour collects on the doubled woollen filters, the red mother-liquor runs into the lower series of vats for further treatment, and in the top vats there remains a residue, which is washed with the water to be used afterwards for the purification. The red filtrates are kept well stirring, and into each vat 12kilos. of zinc-dust, made into a paste with water, are added every 10 minutes—an iron ladleful at a time. Hydrogen sulphide is given off, and the solution becomes colourless. A carboy of ferric chloride (=70kilos.) is then added, and the colour which precipitates at once filtered off. This is termed the *zinc-colour.* The filtrates are allowed to run away.

Purification.—The *raw colour* from six vats, consisting of methylene blue "waste" residue, sulphur, and other impurities, is well stirred up in the upper purification vat, with water which has been warmed to 24°, and to which 18kilos. ferric chloride solution have been added. After standing 12 hours the solution is syphoned off on to the filters, the filtrate precipitated with 200kilos. salt and 30kilos. zinc chloride solution, and the colour then filtered off. A second liquor, containing another 18kilos. ferric chloride, is taken off the residue of the raw colour and treated exactly as the first one. A third extraction is then made, using only 9kilos. ferric chloride; from this the purest and strongest colour is obtained. It is seldom necessary to make a fourth extraction. The residue of the raw colour is then stirred up in a half vat-ful of water with 15kilos. hydrochloric acid, and heated to the boil, sulphurous acid is given off, and the liquid becomes pale or even colourless; 30kilos. ferric chloride are then added and the whole solution filtered into the lower vat, where other 8kilos. ferric chloride are stirred in, and the colour thrown down with 150kilos. rough salt and 30kilos zinc chloride. This is the weakest colour. The *zinc-colour* from six batches is put in the boiling-up vat and well stirred with cold water, and after 12 hours rest filtered into the lower vessel where the colour is thrown down with 10kilos. ferric chloride, 150kilos. salt and 30kilos. zinc chloride, and then filtered off. Instead of a second extraction this residue is generally boiled up with the residue from the raw colour. The purified colour thus obtained is allowed to drain well on the filters, and then is stirred up with cold water until the colour just begins to dissolve; the resulting thick paste is drained in filter bags, wrapped up in strong calico cloths and pressed in the hydraulic press. The cakes are cut up and dried on zinc trays in a stove heated to about 60°. The yield of colour obtained as above is about 5 to 6kilos. per vat.

PROCESS WITH ZINC SULPHIDE.

When hydrogen sulphide is passed into sulphuric acid of 40—50° B., precipitation of sulphur takes place, according to the two following equations: $H_2SO_4 + H_2S = SO_2 + S + H_2O$ and $SO_2 + 2H_2S = 2H_2O + 3S$
When these reactions take place in the presence of sulphate of nitrosodimethylaniline a colourless base containing sulphur is formed, which on oxidation yields methylene blue. The nitrosodimethylaniline is made in three enamelled iron vessels of 400 litres capacity, provided with stirrers and cooling jacket, by stirring 10kilos. dimethylaniline into 75kilos. sulphuric acid of 25° B. (23 strong acid to 50 water), cooling with ice to 6° to 8° and running in slowly a solution of 6·25kilos. $NaNO_2$ in 30kilos. water, whilst stirring well. When this reaction is complete 175kilos. of 60° B. sulphuric acid (150 strong acid to 22·5 water) are poured into each vat. During both operations the temperature must not rise above 12°. The contents are then blown by air pressure into three iron vessels of 1500 litres capacity, provided with covers, pressure gauge, manhole, cooling jacket, draught pipes for removal of gases, and stirrers, which, like the vessels, are covered with lead. Whilst well stirring, 100kilos. of finely ground dry zinc sulphide are gradually added, the temperature being kept at about 20—25°. When all the sulphide has been put in, the vessels are closed and the contents digested at 35—40° until the solution has become colourless. The contents of the three vessels are then blown into a settling vat holding about 3000 litres, well mixed and allowed to stand for 12 hours. The solution is then filtered off from the sulphur, etc., the latter afterwards boiled up with 5kilos. sulphuric acid and 1000 litres water, allowed to settle and filtered. The united filtrates after oxidation are salted out, and otherwise treated as before described. The colour, obtained in this manner is much stronger than that yielded by the "soda waste" process.—T. L. B.

Method for the Spectroscopical Investigation of Tar-colours. P. Schoop. Dingl. Polyt. J. **262**, 424—427.

THE method of testing the strength of dyestuffs by test-dyeing requires great practice, and even then it is difficult in many cases to determine differences of five per cent. with anything like accuracy. The investigations of K. Vierordt and G. Krass have rendered it possible to determine with accuracy and rapidity the amount of colouring matter in a solution. The basis of their method is as follows: Every substance can only absorb those rays of light which have the same rate of vibration as its own molecules, producing, therefore, in the spectrum of the light reflected by it, absorption-bands in certain places. With light from the same source, the absorption-band is the darker the greater the amount of absorbing (coloured) substance is contained in the unity of space, and the relation between the light absorption and the quantity of colouring matter is a very simple one. If $\frac{1}{4}$th of the rays of a beam of light pass through a 1cm. thick stratum of colour solution, a second similar stratum will allow only $\frac{1}{4}$th of this $\frac{1}{4}$th to pass through it, and so on. The same result is obtained if, instead of the light passing through two such layers of solution, it passes through one layer of solution of double strength; in each case the amount of colour is the same. Therefore, if the amount of light which passes through a 1cm. thick layer of a solution containing, say, one milligramme of colour in the litre, be equal to a, then the amount of light which passes through an x-times so concentrated a solution, is $b = a^x$ (where x equals the number of milligrammes of colouring matter in one litre solution), or $\log b = x \log a$ or $x = \log b : \log a$. The quantities a and b are easily and quickly obtained by the spectroscope. Schoop's instrument consists of a tube with slit, prism, and telescope, which is so arranged that any position in the spectrum can be examined and determined. The slit is in two halves, the upper movable and the lower fixed, and immediately in front of the latter is a vessel with parallel glass sides 1cm. apart, for the solution to be tested. When in use, by regulating the height of the solution in this vessel, two spectra are obtained, one of the source of light, and the other the absorption spectrum of the solution. The darkest part of the latter is then found, and the movable slit regulated until the amount of light in each spectrum is equal. The amount of movement is shown on a drum connected with the micrometer screw, and serves as measure for the intensity of the light, that admitted by the fixed part of the slit being taken as unity. Having in this way determined the intensity of light for a normal solution of any colour, a similar determination for the solution to be tested, with the use of the above formula, gives the amount of colour contained in it. It is advisable to regulate the concentration of the solutions so that about 60—70 per cent. of the total light only is absorbed. The apparatus can be used to detect commercial mixtures of two or more colours, as also to determine the end of the reaction in the formation of colouring matters, such as in the magenta and blue melts, etc.—T. L. B.

Toluene di-sulphonic Acids. P. Klason. Ber. **19**, 2887—2890.

BY heating toluene-*m* sulphonic acid with fuming sulphuric acid, two isomeric di-sulphonic acids are formed which can be separated by the different solubilities of their barium salts.

The *first* is identical with the so-called "β" acid isolated by Hakausson (*Ber.* **5**, 1088) from the mother-liquors obtained in the preparation of the α-di-sulphonic acid by further sulphonation of toluene *p*-sulphonic acid. Its barium salt $C_7H_6(SO_3)_2Ba + H_2O$ is a crystalline powder: 100 parts of water at 15° dissolve 3·9 parts of the anhydrous salt. The potassium salt $C_7H\ (SO_3K)_2 + H_2O$ forms readily soluble crystals. The chloride is sparingly soluble in ether and crystallises from carbon disulphide in rhombic tables melting at 96°. The amide is sparingly soluble in water, and melts at 224°.

The *second di-sulphonic acid* is identical with the acid obtained by Limpricht and Richter (*Ber.* **18**, 2177) by reduction of the iodo-toluene-di-sulphonic acid, formed by sulphonation of *p*-toluidine-*m*-sulphonic acid, diazotisation, and treatment with HI. Its barium salt $C_7H_6(SO_3)_2Ba + 3\frac{1}{2}H_2O$ forms easily soluble prisms. The chloride melts at 95° and the amide at 214°.

The author also shows that the so called "γ," di-sulphonic acid of Senhofer (*Ann. Chem. Pharm.* 164, 129) obtained by direct sulphonation of toluene is identical with the above-mentioned α-acid. Hence 5 isomeric toluene di-sulphonic acids are at present known.

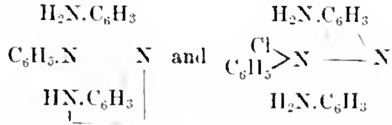
—A. G. G.

Formation of Aniline and Diphenylamine from Phenol. V. Merz and P. Müller. Ber. **19**, 2901—2917.

THE following is a summary of the authors' results:—On heating a mixture of phenol and ammoniacal zinc chloride to a temperature of about 350°, aniline and diphenylamine are obtained, the yield amounting to 70 per cent. of the weight of phenol employed. When sal ammoniac is added to the mixture, the reaction takes place at a lower temperature, and the yield of amines is increased. The best results are obtained at 330°. The main reaction is completed in twenty hours, and the yield in this case is more than 80 per cent. of the weight of phenol used. A small amount of carbonaceous matter is invariably formed. Its quantity increases considerably when the temperature is carried above 340—350°. As to the ratio of aniline and diphenylamine in the product of the reaction, it is shown that the quantity of the latter increases with a diminution in the amount of ammoniacal zinc chloride and sal-ammoniac, if the temperature and period of heating be increased. On heating diphenylamine with sal-ammoniac, or preferably sal-ammoniac and ammoniacal zinc chloride, aniline is formed. When phenol is heated with zinc oxide and sal-ammoniac it yields aniline and diphenylamine, although the amount is less than in the case of ammoniacal zinc chloride. The zinc oxide may be replaced by magnesia, in which case the yield is still further reduced. Sal-ammoniac *per se* has little or no action on phenol at 350°. At a temperature of 400°, however, the action is more energetic, with formation of aniline and diphenylamine. Concentrated hydrochloric acid does not act on diphenylamine at 300°. At 320° a large proportion is decomposed into aniline and phenol.—D. B.

On the Constitution of Safranine. R. Nietzki. Ber. **19**, 3017—3022.

THE author supplements his earlier work on this subject, and discusses the formula lately proposed by Andresen and Bernthsen—viz.:



$$\begin{array}{c} H_2N.C_6H_3 \\ C_6H_5.N \qquad N \\ HN.C_6H_3 \end{array} \quad \text{and} \quad \begin{array}{c} H_2N.C_6H_3 \\ {}^{Cl}_{C_6H_5}{>}N \;\text{—}\; N \\ H_2N.C_6H_3 \end{array}$$

One NH_2 group of (pheno-) safranine can be readily diazotised, and is eliminated by boiling with alcohol. The product $C_{18}H_{13}N_3$ is a dyestuff of bluer shade than safranine, and has no fluorescence in alcoholic solution.

It dissolves in concentrated H_2SO_4 with yellowish-brown colour, which on dilution first becomes green and then red. It forms a well-crystallised double zinc chloride. Its mono-acetyl derivative is violet, and yields yellow crystalline salts.

The second NH_2 group can only be diazotised in strongly acid solution; on decomposition of the product with alcohol a base is obtained which, although as yet not analysed, is in all probability the true mother-substance or basis of safranine. It is reddish-violet, and dissolves in dilute or concentrated acids with a yellow colour. The same colour reactions are shown by di-acetyl safranine, or the mono-acetyl derivative of the base $C_{18}H_{13}N_3$, in which the NH_2 groups, though not removed, are neutralised by acetyl.

By oxidation of 1mol. of symmetrical di-alkyl-*p*-phenylene diamine, with 2mols. of aniline, or of equal mols. of *p*-phenylene diamine, di-alkyl aniline, and aniline, isomeric di-alkyl safranines are obtained.

Both products allow themselves to be readily converted into blue di-acid diazo-compounds. The explanation of these facts by either of the above formulæ appears to offer some difficulty.—A. G. G.

Improvements in the Production of Mixed Azo-colours. C. A. Martius, Berlin, Germany. Eng. Pat. 2213, February 15, 1886. 6d.

THE inventor has discovered that when salts of tetrazodiphenyl and its homologues act upon amines and phenols or their sulphonic acids, only one molecule of these compounds combines in the first place with one molecule of the tetrazo-salt, leaving one diazo-group free, so that combination is possible with a second molecule of the same or a different amine, phenol or sulphonic acid. By this means a series of secondary azo-colours, containing similar or dissimilar radicles, can be prepared, a list of available amines, phenols, sulphonic and carboxylic acids being given in the specification. The general process of manufacture consists in combining one molecule of the tetrazo-salt with one molecule of the amine, phenol, etc., and then combining this intermediate product with the second molecule of the amine or phenol. The following examples of mixed azo-colours are given:—(1) Tetrazodiphenyl, α-naphthol-sulphonic acid and α-naphthylamine-sulphonic acid; a brown violet. (2) Tetrazodiphenyl, β-naphthol-disulphonic acid R and β-naphthylamine-sulphonic acid. (3) Tetrazoditolyl, α-naphthol-sulphonic acid and β-naphthol-sulphonic acid R. (4) Tetrazoditolyl, α-naphthol-disulphonic acid and β-naphthol. (5) Tetrazodiphenyl, sulphanilic acid and salicylic acid; dyes cotton yellow from a soap bath. (6) Same constituents as in last sample, but order of combination reversed. (7) The sulphanilic or salicylic acid of 5 and 6 replaced by amidobenzoic acid. (8) Naphthionic acid replaced by amidobenzoic acid. (9) Tetrazodiphenyl-sulphonic acid, β-naphthylamine and β-naphthylamine-sulphonic acid. (10) Tetrazoditolyl-disulphonic acid, α- and β-naphthylamines.—R. M.

Preparation of Paramidodiphenyl-sulphonic Acid. T. Carnelly, Dundee. Eng. Pat. 3890, March 16, 1886. 6d.

THIS acid is prepared by treating benzidine with four times its weight of ordinary oil of vitriol and heating the mixture to 130° C. for about 30 minutes. The product, when cool, is mixed with water, and the precipitated acid collected and washed. This sulphonic acid can be used for the preparation of azo-dyes according to the known processes.—R. M.

Process for the Production of Azo-colours from Ortho-sulpho- or Orthocarbo-Acid of Benzidine. C. D. Abel, London. From the "Actiengesellschaft für Anilin Fabrikation," Berlin, Germany. Eng. Pat. 13,780, Oct. 27, 1886. 6d

THE acids referred to in this specification are prepared by reducing metanitrobenzene-sulphonic and metanitrobenzoic acid in alkaline solution with zinc dust, whereby hydrazo-compounds are first produced, and these, by the action of acids, are converted into the isomeric benzidine-disulphonic or dicarboxylic acid, just in the same manner as benzidine is produced from hydrazobenzene. These two acids can then be used for the preparation of azo-colours, of which the following are given as examples:—(1) Benzidine-disulphonic acid (diazotised) and β-naphthol, a yellowish red; (2) the same tetrazo-compound and α-naphthol-sulphonic acid, a bluish red; (3) the same tetrazo-compound and diphenylamine; (4) the same tetrazo-compound and α-naphthylamine; (5) the same tetrazo-compound and naphthionic acid; (6) benzidine dicarboxylic acid (diazotised) and α-naphthol-sulphonic acid, bluish red; (7) the same tetrazo-compound and α- and β-naphthylamine-sulphonic acid, yellowish brown.—R. M.

Improvements in the Manufacture of Colouring Matters, and Vehicle therefor. A. M. Clark, London. From Dr. A. Müller-Jacobs, New York, U.S.A., through Wirth & Co., Frankfort-on-Main, Germany. Eng. Pat. 2878, Feb. 27, 1886. 6d.

THIS invention is carried out by first preparing a neutral resin soap, dissolving in water, and precipitating by adding a solution of zinc or aluminium sulphate, or any

other salt of a metal. The precipitate is washed and dried, and then forms a fine powder consisting of the "resinate" of zinc, aluminium, etc. This "resinate" is coloured by adding a colour solution to the solution of the soap, or to the solution of the metallic salt before precipitation, or by washing the dry powder with an aqueous or alcoholic solution of the colour. The coloured resinates are said to be soluble in benzene, carbon disulphide, etc., oils and oil varnishes, and can be applied for varnishes, printing inks, dyeing and printing, etc.
—R. M.

A Process for the Production of Mixed Azo-colours from the Diamido Combinations of the Ethers of Diphenol. C. A. Martius, Berlin, Germany. Eng. Pat. 7283, May 31, 1886. 6d.

THE patentee has discovered that the diamido-derivatives of dimethoxy- and diethoxy-diphenyl may be used for the production of mixed azo-colours in a manner similar to benzidine and its homologues. The colouring matters are produced by combining first 1 molecule of an amine, phenol, or their sulphonic or carboxylic acids, with the tetrazo-salt of the methoxy-base, and then combining this intermediate product with 1 molecule of the same or a different amine, phenol, etc. Two examples of the process are given. 1. Tetrazodiethyldiphenol-ether is combined with 1 molecule of β-naphtholdisulphonic acid (R) (*Ber.* 17, 462; see also this Journal, 1884, 245), and the product is then combined with 1 molecule of α-naphtholmonosulphonic acid, when a blue colouring matter is produced. 2. In the preceding example the α-naphtholsulphonate is replaced by an equivalent quantity of sodium naphthionate, when a violet colour is formed. The sulphonic acids of the methoxy- or ethoxy-base may be used instead of the bases themselves.—R. M.

V.—TEXTILES: COTTON, WOOL, SILK, Etc.

An Improved Manufacture of Artificial Silk-like Filaments from Viscous Liquids, and Apparatus for that purpose. Comte H. de Chardonnet, Besancon Doubs, France. Eng. Pat. 2211, Feb. 15, 1886. 8d

THIS invention relates to the manufacture of artificial filaments resembling silk, by forcing, at a pressure of 2 to 3 atmospheres, a viscous solution of cellulose-nitrate in ether-alcohol through a fine jet made of glass, and subsequently through a current of water, where it solidifies. The filament is seized by a delicate pair of pincers and led over a reel or bobbin.—E. J. B.

Improvements in Waterproofing Fabrics. G. F. Redfern, London. From E. Chevallot, Bordeaux, France. Eng. Pat. 3095, March 4, 1886. 6d.

THE fabrics or other material to be treated are passed through a bath containing soap and a compound of caseïn and lime. When thoroughly saturated they are withdrawn, and freed from excess of the solution by passing them between rollers. They are then dipped in a bath of acetate of alumina, afterwards immersed in boiling water, or dried and hot pressed. Full directions are given for the preparation of the different baths employed.—E. J. B.

Improvements relating to the Treatment of Fibre, and to the Manufacture of Imitation Straw Plait therefrom. C. and J. Halter, Mellingen, Switzerland. Eng. Pat. 14,647, Nov. 12, 1886. 4d.

THE imitation straw plait is made from the flat ribbon-like bast of the Raphia. The fibre is boiled in a weak solution of caustic soda, washed, treated with dilute hydrochloric acid, and again washed. The fibre is then cut into narrow strips, which are tied together and wound upon bobbins. If desired, the strips can be bleached with hydrogen peroxide. The strips are then made into a round or flat plait in the ordinary manner. The plaits may be made upon cotton or other threads, or upon brass or steel wire in order to render them sufficiently stiff.—E. J. B.

VI.—DYEING, CALICO PRINTING, PAPER STAINING, AND BLEACHING.

Improvements in Dyeing Tissue and other Papers, and in Apparatus therefor. J. Fletcher, Stoneclough, Manchester. Eng. Pat. 13,598, Oct. 25, 1886. 6d.

HITHERTO, owing to the manner in which pulp for tissue paper has been dyed, there has been a very considerable waste of colouring matter, and also a want of brilliancy in the coloured paper produced. This patent relates to mechanical arrangements for dyeing paper after manufacture, by pressure, which forces the colouring agent through the fibres of the paper. At the same time it is claimed that, besides being more economical, this method produces richer and darker colours than is possible when paper pulp is dyed in the engine.
—H. A. R.

VII.—ACIDS, ALKALIS, AND SALTS.

Manufacture of Potassium Sulphate and Ammonium Chloride from Potassium Chloride and Ammonium Sulphate. K. Schmidtborn. Chem. Zeit. **10**, 1499.

Mutual Decomposition of the Raw Materials—The apparatus consists of a large round lead-lined tank, which is provided with a false bottom, covered with filter cloth, a mechanical agitator, and a leaden steam coil. 2½ tons of ammonium sulphate are put into the tank and dissolved in water to a solution of 1·142 sp. gr. This is heated to a boil, and while the boiling is kept up, an equivalent quantity of potassium chloride (95—97 per cent. KCl) is gradually added, and the agitator set in motion. The mutual decomposition commences at once, and potassium sulphate is precipitated in an amorphous state. In the short time of 10 minutes after the addition of all the potassium chloride, the decomposition is complete, when the agitation is discontinued, and the mixture allowed to settle for one hour.

Production of Potassium Sulphate and its Purification.—The hot liquor is then run through a tap at the bottom into a lead-lined cooling vessel, whilst the precipitate of potassium sulphate remains in the tank on the filter cloth, where it is systematically washed with warm water, until it only contains up to a half per cent. of ammonium salts. In this manner 70 per cent. of the total potassium sulphate is directly recovered. The washings are employed for dissolving new quantities of ammonium sulphate.

Treatment of the Filtered Liquor.—The liquor in the cooling vessel is allowed to crystallise, yielding another crop of potassium sulphate, which is purified by washing with water. The mother-liquor is concentrated until potassium sulphate is plentifully salted out; and the salts thus obtained are washed, together with those left on the filter of the dissolving vessel. The hot concentrated liquor is filtered and allowed to crystallise slowly. After several days the mother-liquor is run into a reservoir, and boiled down along with other liquors of the same origin. The crystals obtained consist of two different layers, which are quite distinct from each other, and are easily separated. The top layer, about three-fifths of the total bulk, consists of 94 per cent. ammonium chloride, and 6 per cent. foreign salts, principally potassium sulphate and chloride, and sodium sulphate and chloride, whereas the bottom layer is composed of 78 per cent. ammonium chloride and 22 per cent. potassium sulphate. The top crystals are pure enough to be further purified by washing, whilst the bottom salts are treated with the washings of the potassium sulphate obtained at a previous stage of the process. These washings, containing both ammonium chloride and potassium sulphate, are heated to 100° C., and the crystals, placed in perforated drums, are suspended in the hot liquor. The ammonium chloride dissolves almost immediately, whilst potassium sulphate is only sparely dissolved and is left behind on the drums in a state to be easily purified by washing. The hot washings, after cooling, deposit pure ammonium chloride, and the mother-liquor is used over and over again for the same purpose. Both the potassium sulphate and ammonium chloride are jigged in a hydro-extractor, the former being then ready for being packed; whereas the latter requires drying in a heated chamber. It is claimed for this process that the potassium sulphate produced is worth more than the potassium chloride employed, that no hydrochloric acid is necessary for the ammonium chloride, which, moreover, is directly obtained in a pure state without expensive refining, and that the manufacture of ammonium chloride is not dependent on the proximity of a gas works—*i.e.*, a cheap supply of ammoniacal liquor.—S. H.

A New Process for the Preparation of Crystallised Carbonates. L. Bourgeois. Compt. Rend. **103**, 1088.

THE process is based upon the precipitation of superheated solutions of salts by ammonium carbonate. If the solution of an ammonium salt, in which a carbonate is suspended, be boiled, the latter gradually dissolves, changing into ammonium carbonate. If the heating be performed in a sealed tube, ammonium carbonate collects in the empty part of the tube, and on cooling a re-formation of the original carbonate takes place, which is, however, deposited in a crystalline state. In this manner the author prepared artificially calcite, strontianite, witherite, and cerussite. Cadmium carbonate, which was previously only known as an amorphous body, was thus obtained in rhombohedral crystals, whereas the carbonates of lithium, magnesium, zinc, manganese, iron, nickel, cobalt, and copper could only be produced in the amorphous state. If the solution of an ammonium salt be heated with the equivalent quantity of urea in a sealed tube, at 140° C., at which temperature the latter is decomposed to ammonium carbonate, the formation of the crystallised carbonates takes place suddenly.—S. H.

Improvements in obtaining Ammonia and Hydrochloric Acid from Ammonium Chloride. L. Mond, Northwich. Eng. Pat. 65, Jan. 2, 1886. 6d.

AMMONIUM CHLORIDE is volatilised and its vapour passed over nickel protoxide while heated to about 400° C. The chlorine then combines with nickel, ammonia being set free, and passing on, can be utilised in any convenient manner. Superheated steam of about 450° C. is then passed over the heated nickel chloride, when a re-formation of nickel protoxide takes place, while the chlorine is given off in the state of hydrochloric acid gas, which can be condensed by the usual methods. The nickel protoxide is thus again in a state to decompose ammonium chloride. Besides nickel, a large number of the oxides of heavy metals possess the property of decomposing ammonium chloride in the manner stated. For carrying out this invention, a number of cast-iron retorts are set obliquely in one common furnace, and heated by direct fire or generator gases. The retorts pass through the walls of the furnace at both sides, and are at both ends provided with covers and openings for the inlet and outlet of the gases.—S. H.

Improvements in obtaining Ammonia and Chlorine from Ammonium Chloride. L. Mond, Northwich. Eng. Pat. 66, Jan. 2, 1886. 6d.

THIS patent is a modification of Eng. Pat. 65, 1886 (see preceding abstract), by the same inventor. Vapours of ammonium chloride are passed over nickel protoxide heated to 400° C., when nickel chloride is formed and ammonia is set free. Air previously dried and heated to 500° C. is then passed over the heated material, when the oxygen combines with the nickel, forming an oxide of nickel, and the chlorine is given off in an uncombined state. The nickel oxide can be used over again for the first stage of the process. The gas given off in the second stage is said to contain from 5 to 7 per cent. of chlorine.

Oxides of other heavy metals possess similar properties as nickel oxide. The apparatus recommended is practically the same as that described in the abstract of Eng. Pat. 65, 1886.—S. H.

IX.—BUILDING MATERIALS, CLAYS, MORTARS, AND CEMENTS.

The Influence of an Addition of Sugar on the Solidity of Cement. Th. Hankey. Glaser's Ann. 1886, **19**, 187.

EQUAL parts of finely ground lime and brown sugar are said to form a mortar equal in strength to Portland cement. According to R. Cornish, it has been the custom in India to add a certain amount of raw sugar to mortar; and works made with such mortar can hardly be destroyed, except by blasting. The celebrated Chunam polished walls of Madras are said to have been made with a cement to which sugar was added, a slight addition improving the quality of cement appreciably.—T. L. B.

X.—METALLURGY, Etc.

Phosphorus Compounds in Pig-iron. Leopold Schneider. Oesterr. Zeitsch. f. Berg. u. Hüttenw. **34**, 735.

THE author has treated various kinds of crude iron (specular, white, and grey pig-iron, ferro-manganese etc.) with aqueous copper chloride solution, which has little action on phosphorised iron, and has examined the washed residue. In 100 parts of iron he obtained—

18·6	phosphorus	—	manganese	18·5	phosphorus	—	manganese
18·6	,,	—	,,	20·5	,,	5·7	,,
18·2	,,	—	,,	37·7	,,	52·8	,,
18·2	,,	—	,,	38·8	,,	54·4	,,

From these numbers he concludes that phosphorus forms with iron a compound Fe_3P, but with manganese the compound Mn_3P_2. The same compounds are no doubt present in steel and wrought-iron, although they could not be separated from the latter, because of the small quantity of phosphorus contained therein.—A. R.

Improvements in the Means of and Apparatus for the Extraction of Metals from their Ores, particularly in the Treatment of "Blue Stone" and similar Complex Ores, and for Electrolytically Refining Copper, and for the Manufacture of Sulphuric Acid by Electrolytic Action. W. & A. S. Elmore, London; and H. Barrett, Dulwich. Eng. Pat. 15,988, Dec. 29, 1885. 6d.

FOR the treatment of ores containing zinc, lead, copper, silver, gold, iron, sulphur and gangue, the process is as follows:—The finely-crushed ores are roasted in a reverberatory furnace with free access of air, the gaseous products being led into a condensing chamber where, mixed with steam, they pass between pairs of suitable platinum combs insulated from each other, and connected with opposite poles of an electrical machine. The ozone produced by the discharge acting on the sulphur dioxide of the gases in the presence of steam, forms sulphuric acid, which condenses at the comparatively low temperature of the chamber, and may afterwards be concentrated. The roasted ore is next agitated with water or dilute acid to dissolve copper and zinc, which are generally accompanied by iron and some silver. The copper and silver are then precipitated with metallic zinc, washed free from the latter metal, and cast into anodes. The solution of iron and zinc is, if necessary, freed from excess of the former by the addition of calcium carbonate, air being forced through the liquid during the precipitation. It is then electrolysed for zinc, with lead anodes and zinc cathodes in tanks provided with an inlet pipe at the bottom and an outlet above, through which a circulation is effected to rectify the increasing acidity of the bath whilst zinc is deposited; the more acid liquid leaving the tanks is returned to the roasted ore, and becoming saturated, passes through the above cycle of operations before re-entering the tank. The residue from the leaching vats is treated in the usual way for lead, silver and gold. The argentiferous copper anodes are used in a vessel divided into two compartments by a porous partition. This vessel is first filled with solution of cuprous chloride in hydrochloric acid or brine, from which copper is constantly deposited on the cathode, and into which, but in the other compartment, the copper and silver of the anode dissolve.

When sufficiently treated, the silver is exactly precipitated by means of a soluble iodide, and the filtered solution of copper is returned to the cathode side of the vessel.—W. G. M.

Improvements relating to the Recovery of Tin from Scraps of Tinned Plate. H. H. Lake, London. From Wirth & Co., Frankfort-on-the-Maine. Eng. Pat. 2402, Feb. 18, 1886. 6d.

In recovering the tin from the mixed solutions of stannous and ferrous chlorides resulting from the treatment of the plate with hydrochloric acid, the liquid is to be agitated with finely-divided calcium carbonate until the tin is completely precipitated as oxychloride, thus :—

$$2SnCl_2 + 3H_2O + CaCO_3 = SnO.SnCl_2.3H_2O + CO_2 + CaCl_2.$$

This operation is to be performed in closed vessels in an atmosphere of carbon dioxide to prevent precipitation of the iron. The insoluble tin salt is then filtered under pressure, and the precipitate suspended in water in a closed vessel as before, and boiled with another equivalent of calcium carbonate, by which means pure stannous oxide may be obtained :—

$$SnO.SnCl_2.3H_2O + CaCO_3 = 2SnO + 3H_2O + CO_2 + CaCl_2.$$

From the calcium ferrous chloride filtrate the hydrochloric acid and ferrous sulphate may be recovered by treatment with sulphuric acid after evaporation to dryness.—W. G. M.

Improvements in the Manufacture of Iron and Steel. J. H. Johnson, London. From La Société Anonyme de Commentry-Fourchambault, Paris. Eng. Pat. 2867, Feb. 27, 1886. 6d.

The object of this invention—namely, to obtain a good metal from impure mixed scrap—is accomplished in four stages. Firstly, the scrap is melted in a special circular gas regenerative furnace with basic lining and spherical roof; with the charge is added a limestone flux and subsequently a pure oxide of iron; thus silicon is completely eliminated. Secondly, sulphur is removed by the addition of a suitable proportion of a ten per cent. spiegel, with soda and lime or similar mixture, at an increased temperature. Thirdly, the metal is tapped into a deep ladle, with a lime and soda lining above the usual refractory materials, wherein the last traces of sulphur are extracted, and by which the iron is conveyed to a basic Siemens furnace of ordinary construction. Finally, in this latter furnace the phosphorus and carbon are eliminated in the usual way, manganese is added and the metal poured as in the Siemens process.

—W. G. M.

A Process for Deoxidising Metals. P. Jensen, London. From The Deoxidised Metal Company, Bridgeport, Connecticut, U.S.A. Eng. Pat. 7796, June 10, 1886. 6d.

Homogeneous, hard, sonorous and sound castings are made by adding to the melted metal a depth of one or two inches of horn (or hide) clippings, or analogous material. In casting bronze or brass the addition is made after the fusion of the copper and prior to the introduction of tin or zinc. The alloy thus produced is to be called "deoxidised bronze."—W. G. M.

Improvements in the Manufacture of Mineral Wool and in Apparatus therefor. J. T. King, Liverpool. From H. Kennedy, Sharpsburg, Pennsylvania, U.S.A. Eng. Pat. 15,154, Nov. 22, 1886. 8d.

A wool, consisting almost wholly of fibre, and therefore requiring no separation from shots, is made by surrounding the stream of molten slag with jets delivering steam or air in such manner that a swirling motion is given to the slag, which thus becomes more perfectly converted into fibre. The jets are preferably in the form of vertical and horizontal slots, so disposed at different angles as to impart the desired motion to the liquid.—W. G. M.

Improvements in Making Steel. J. T. King, Liverpool. From D. Brose, Pittsburgh, Pennsylvania, U.S.A. Eng. Pat. 15,357, Nov. 25, 1886. 4d.

In order to ensure a thorough mixture of the final charge of ferro-manganese or spiegel with the iron after treatment in the Bessemer converter, limestone is added with the manganese, by which a violent ebullition is caused. Of preference a calcareous marl from Western Pennsylvania should be employed, and should be introduced with the manganese into the empty ladle, before the contents of the converter are poured into it.

—W. G. M.

XI.—FATS, OILS, AND SOAP MANUFACTURE.

Experiments on the Preservation of Pig Fat in Ointments. E. Mylius. Pharm. C.H., N F. **7**, 533.

Since there is a tendency to abandon the use of vaseline in ointments in favour of animal fats, these experiments have just now a special interest. After experimenting with the most diverse preservatives, the author finds that the best results are given, for lead ointment with 3 per cent. of boric acid, and for potassium iodide ointment with 10 per cent. of glycerin and 0·1 per cent. of oil of cloves.—W. G. M.

Improvements in the Preparation or Treatment of Oils for use in treating Wool, in the Manufacture of Soap and Lubricants, as Mordants for Dyeing, and for analogous uses. J. Y. Johnson, London. Eng. Pat. 449, Jan. 11, 1886. 6d.

By this invention heavy hydrocarbons or mineral oils, of the type C_nH_{2n+2}, can be oxidised so as to produce saponifiable oils. To produce the effect the mineral oil is heated to about 160° C., with a varying percentage of oxyoleic acid, or with any very rancid animal or vegetable oil. Resin oils may be similarly treated. Another process, to be used alone, or in combination with the above, consists in passing a current of gaseous chlorine through the oil, oxides of the alkalis or of the alkaline earths being also present. Oils thus oxidised, with the addition of from 2 to 10 per cent. of fixed vegetable oils, may be employed as mordants in dyeing vegetable fibres.

—W. L. C.

Improved Method and Apparatus for obtaining Alizarin Oil from Oleaginous Seeds. A. Bruenstein, Moscow, Russia. Eng. Pat. 510, Jan. 12, 1886. 11d.

The seeds are decorticated, crushed in a roller mill, and there thoroughly incorporated with from 40 to 60 per cent. of sulphuric acid, distributed from a leaden and glass box, care being taken that the temperature does not rise above 50° C. After the mass has lain some hours in a lead-lined tank, much oil collects at the surface. After the removal of this the mass is stirred up with water, and after subsidence, more oil is removed. Oil thus prepared is said to be 10 per cent. better than the ordinary alizarin oil prepared from *Ricinus*, and the cost of preparation to be from 2s. to 4s. per pound less. Drawings are given.—W. L. C.

Lubricants for Steam Cylinders. J. Dewrance. Eng. Pat. 2178, Feb. 15, 1886. 4d.

Plumbago alone, as a lubricant in marine engines, is often washed away by the condensed water. The patentee, therefore, mixes it with an insoluble soap of lead or lime.—W. L. C.

An Improved Process for the Saponification of Fatty Bodies. E. Edwards. From L. Rivière, Paris, France. Eng. Pat. 2762, Feb. 25, 1886. 8d.

The novelty of the process consists mainly in the apparatus (a drawing of which is given) employed for the purpose of mixing fats with (1) alkalis for the production of hard and soft soaps; (2) milk of lime for the ultimate production of stearic acid; (3) sulphuric acid; (4) steam

or aqueous vapour alone. Two supply tanks hold the liquids to be mixed (for soaps, fat at 80° C., and alkaline ley at 10 per cent. strength and 80° C.), whence the liquids run into an "integrator" and thence into a reaction vessel. All the vessels are air tight, and communicate with each other by pipes furnished with cocks to regulate the flow of the liquids. For some purposes a series of integrators and reaction vessels is provided.
—W. L. C.

Making Self-extinguishing Candles. R. Ashton, Heaton Mersey, near Manchester. Eng. Pat. 9294, July 17, 1886. 8d.

DIVIDERS—*i.e.*, hollow cones or discs, or saucer-shaped pieces of non-combustible material (usually tin plate)—are attached to the wick before the combustible material is put round it. These dividers are kept in their places by fine wire, twisted on the wick. This arrangement extinguishes the flame when the latter burns down to it.
—W. L. C.

The Treatment of Spent Soap Lyes, Crude Glycerine, and other Solutions containing Glycerin, for the Removal of Impurities and the Recovery of Glycerin and other Products therefrom. G. H. Allen, Sheffield, and B. Nickels, London. Eng. Pat. 11,069, August 31, 1886. 6d.

THE patentees claim the use of a soluble salt of copper (either cuprous or cupric) for the precipitation of impurities from the lyes, which may or may not be subjected to a preliminary purification by treatment with acid, and with an iron salt. The precipitates thus formed are separated by subsidence or filtration, and the copper recovered therefrom by roasting and treatment with sulphuric acid. Instead of using iron and copper salts, a current of electricity (E.M.F. at least 4 volts) may be passed through the lyes, with an anode of iron or iron alloy, and copper or copper alloy.—W. L. C.

An Improved Wash or Dip for Sheep and other Animals, the same being applicable for Washing Fabrics or other Materials. A. MacArthur. Eng. Pat. 14,984, Nov. 18, 1886. 4d.

NAPHTHA, soft soap, and pearl ash, with or without the addition of ether, benzene, benzoline, or creosote, are mixed and diluted with water.—W. L. C.

XII.—PAINTS, VARNISHES, AND RESINS.

An Asphaltic Protective and Preservative Covering for the Decks of Ships and similar Craft, and Methods of treating and applying the same. E. F. Wailes, Newcastle-on-Tyne. Eng. Pat. 2060, Feb. 12, 1886. 6d.

THE covering consists essentially of asphalt or bitumen (natural or manufactured), or of asphaltic or bituminous compositions, in which asphalt or bitumen forms the chief ingredient, treated by two different processes, termed by the inventor the dry and liquid process respectively. In the dry process, the asphalt or bitumen, or compound containing one of these substances, is ground to powder and roasted in a furnace; then, the ship's deck having been rendered perfectly clean and dry, and holes or defective places having been filled up or made level, the powder is spread, whilst hot, over the surface to the required thickness, and consolidated by applying heavy weights by a roller or otherwise. The surface may then be smoothed by the application of heated irons—flat or as rollers—and, if necessary to give a firm footing, it may afterwards be sprinkled with sand, powdered granite, or any gritty substance, etc. According to the liquid process, the asphalt or bitumen or composition is melted in a furnace boiler, together with oil, coal-tar, pitch, etc., in such proportions as to give the consistency required for the conditions under which it is to be used, especially having regard to the changes or temperature to which it may be exposed. Being thoroughly melted and mixed, the composition is run on to the surface of the deck, in its heated state, the deck having been previously prepared and cleaned as above described. When set, or nearly so, the surface of the composition may, if required, be consolidated and smoothed by application of a roller, or may be treated by sprinkling sand, powdered granite, etc., upon it.—E. G. C.

Improvements in obtaining Pigments. D. Swan, Braeside, N.B. Eng. Pat. 2310, Feb. 17, 1886. 4d.

ONE of the objects of this invention is the utilisation of ferrous chloride arising in the galvaniser's and other industries, but it is also advantageously applicable when the protochloride is specially made for the purpose of producing pigments. The solution of ferrous chloride is mixed with carbonate of lime or some other alkaline earthy carbonate, and the mixture is submitted to agitation and aëration. The result of the operation is to form a solution of chloride of calcium or other metal, and a precipitate which is of a yellow colour, and well suited for use as a pigment. If the mixture contain as much ferrous chloride as corresponds to 56 parts by weight of iron with 100 parts by weight of carbonate of lime, the resulting pigment will be of a deep yellow colour inclining to orange, whilst if there be a larger proportion of carbonate of lime the colour will be a pale or lighter yellow. If a red colour is desired it can be obtained, as is well known, by heating or calcining the deep yellow pigment, the result being a pure oxide of iron. The precipitated pigment is finished by washing and drying; whilst the chloride may be utilised in any known way.—E. G. C.

An Improved Anti-fouling Composition for Ships' Bottoms. W. Carter, Sunderland. Eng. Pat. 15,561, Nov. 29, 1886. 4d.

THE composition is prepared in two forms, one of which is for a priming or first coat, which protects the iron from corrosion, and the other for application on the top of the first, forming a second coat. The "priming" or first coat consists of the following ingredients in approximately the proportions given—viz., for 112lb.: pure zinc, 20lb.; "Turkey red," 6lb.; resin, 39lb.; mineral turpentine, 15lb.; and boiled oil, 32lb. The second coat consists of the following constituents:—For 112lb: "Turkey red," 20lb.; mineral green, 10lb.; resin, 30lb.; mineral turpentine, 25lb.; and boiled oil, 27lb. The ingredients in each are mixed in a furnace pot—the zinc and Turkey red in the first coat, and the Turkey red and mineral green in the second coat—with boiled oil; then the resin, having been dissolved, is added, and the consistency is further reduced by the boiled oil. After cooling, the turpentine is added, and the whole thoroughly mixed and stirred, and put into casks for use.
—E. G. C.

XIII.—TANNING, LEATHER, GLUE, AND SIZE.

Treating and Preserving Hides and Skins. E. A. Brydges, Berlin, Germany. Eng. Pat. 14,946, Nov. 17, 1886. 4d.

THIS invention consists in the application of "fossil-meal" or "Kieselguhr" for preserving hides or skins during transport from putrefaction or the attacks of insects. Raw fossil-meal, simply dried, can be used, or it may be calcined either in absence or presence of air. The calcined meal is extremely hygroscopic, absorbing the moisture of the hides or skins. The hides to be dried are spread out on a layer of fossil-meal, and covered with a second layer of it.—B. H.

An Improved Process of Tanning. H. H. Lake, London. From A. Millochau and F. Chailly, Paris, France. Eng. Pat. 15,200, Nov. 22, 1886. 6d.

THE chief object of this invention is to shorten the time of tanning. The tanning is effected in a pit of ordinary construction, and air is injected at the bottom of each pit through a pipe connected with a fan. The hides are suspended from bars at the upper part of the pit, which can be hermetically closed by a hinged cover or other means. The air can be drawn from the top of the pit by the pump, and injected again at the bottom, or fresh air can be injected. The liquor can be prepared in the same pit as the hides by introducing the material and water, or it may be prepared in another pit fitted with the air injecting apparatus.—B. H.

XIV.—AGRICULTURE, MANURES, Etc.

On Manures. K. H. Neuffer. Chem. Zeit. **10**, 1057.

THE author has observed that sugar-beet, growing in clayey marl, was improved by manuring with potassium phosphate. The amount of sugar also increased. Potassium phosphate is probably advantageous as a manure in soil rich in lime, raising both the quantity and quality of the plant. The author then remarks on the different action of potassium phosphate and superphosphate as manures. The latter, moreover, usually contains chlorine, and in dry seasons this is sometimes very disadvantageous. Manure containing sulphates must not be used in soil rich in gypsum. Potassium phosphate has no effect in soil containing much potash and little lime. In such soil, Thomas-slag, etc., should be employed.—A. R.

Treatment of Thomas-slag. L. Blum. Chem. Zeit. **10**, 1556.

TO avoid grinding the slag it is proposed to act on the fluid slag, as it runs out of the converter, with a jet of steam, under a pressure of 2—4 atmospheres. It is a well-known fact that slag-wool is made in this way, but Thomas-slag always contains a large excess of lime, so that the slag is reduced to a fibrous and powdery mass, which needs no further disintegration for manuring purposes. Should the slag be very fusible (when fluorspar or alkalis have been added), it can be run off into a waggon, and then treated with steam. With regard to the chemical action of the aqueous vapour, it is found that the metallic granules are oxidised, and some of the sulphur is eliminated as H_2S.—A. R.

XV.—SUGAR, GUMS, STARCHES, Etc.

Purification of Syrups and Molasses. Journ. Fabr. Sucre, **27**, 46.

DUREAU describes a method, successfully employed at Bresles, for purifying syrups and molasses. The green syrup is treated according to purity, amount of sugar it contains, and alkalinity with dilute hydrochloric acid and milk of lime, of 25° B., then boiled up with steam, diluted to 2—3°, again heated to 75°, and filtered through Puvrez's sack-filter. A quantity of the thin purified juice corresponding to about 40kilos., is now introduced, by means of the forcing pump, into the fourth diffuser. The diffusion battery has 12 vessels of 25 hectolitres capacity. In a charge, 77 vessels are filled with 1280kilos. of beet, and each time 1800 litres of liquid extract of 4° B. are drawn off. The rest of the process is that usually adopted. At Bresles 5 per cent. of the syrup, reckoned on the weight of the beet, is returned to the extract, and a yield of 1 per cent. higher in sugar is thus obtained without any extra outlay.—A. R.

Abnormal Beet and the Quantity of Pulp in the same. Deutsche Zuckerindustrie, **11**, 1778.

IN consequence of the frequent assertions that beet poor in juice contains only 88—90 per cent. of the latter, whence it should follow that there must also be 10—12 per cent. of pulp, Lippmann has made several direct determinations of pulp in such beet, and the results agree with previous analyses of other chemists. In examining 38 separate specimens of beet, certified poor in juice, the amount of pulp was in 3 cases less than 4 per cent., and in 30 cases less than 5 per cent.; the heads of very big beet contained no more pulp than the rest of the beet (always below 5 per cent.); normal and spuig beet, after lying for a week in the store, had hardly gained 1 per cent. in pulp. The so-called lack of juice can therefore not be due to the quantity of pulp in the beet, but only to its quality. In determining the quantity of pulp, the temperature of the extracting medium has a considerable influence on the results obtained; thus water of 60°, 80 and 100° gave 4·63, 4·12, 3·72 per cent. pulp respectively.—A. R.

Purification of Beet Juice with Aluminium Bisulphite. Suchomel. Deutsche Zuckerind. **11**, 1820.

BEET JUICE is doubly saturated with 3 per cent. of lime, carbonic acid being passed in simultaneously. Saturation is carried to within 0·02 of alkalinity. For every 3000 litres of this juice 1 litre of the bisulphite solution is added; the syrup of 20—24° B. is treated for every 2000 litres with 4—5 litres of the bisulphite, then with 1 litre milk of lime, and saturated to 0·08—0·10, then passed through filter-presses and boiled down. The bisulphite solution had a sp. gr. of 20—24° B., and contained 6·73 per cent. SO_2, 1·12 per cent. SO_3, 3·34 per cent. alumina, and was able to neutralise about 0·1 potash or soda alkalinity. The favourable action of the bisulphite is not one of purification but of decolourisation, and juice thus treated has an extraordinary lustre and is only slightly alkaline. Very little sulphuric acid passes into the juice, so that the boiled sugar mass and the sugar are very much freer from gypsum than when calcium bisulphite or SO_2 gas are employed, the efficiency of which cannot, moreover, be determined so readily.—A. R.

The Amount of Saltpetre contained in Sugar Beet. Sucrerie Indigène, **28**, 489.

FAUCHER has recently drawn attention to the large amount of nitrates, especially saltpetre, contained in beet, and he gives analyses by Ladureau and Corenwinder, according to which the quantity of nitrates in the beet is practically independent of the nitrates contained in the manure. Thus the former analyst found in 100kilos. of beet, grown in soil manured with nitrates, 113grms. saltpetre, in soil manured with stable manure 305grms. saltpetre. The nitrates pass into the molasses and from these into the osmose-water, so that by evaporating and crystallising the latter, crystallised salts containing 46—50 per cent. saltpetre can be prepared, which is of course a very useful by-product.—A. R.

Analysis of the Filter-press Cake from the Manufacture of Sugar from Beet Root. Sidersky. Bull. Ass. Chim. **4**, 295.

THE press-cake contains soluble and insoluble sugar. In order to determine the quantity of each kind, two samples of the cake, each weighing 16·2grms., are ground with about 50cc. of water to a homogeneous paste. One sample is put directly into a 100cc flask, treated with a little basic lead acetate, made up to 100cc., filtered and polarised. To the other sample, acetic acid is gradually added, stirring continually, until the reaction is just neutral and a light scum appears on the surface. It is then treated with lead acetate and so forth, as mentioned above. The result of the first polarisation represents the soluble sugar, that of the second the total sugar; the difference of both results is the insoluble sugar.—S. H.

XVI.—BREWING, WINES, SPIRITS, Etc.

Barley for Brewing Purposes. Maerker. Wochensch. f. Brauerei, 1886, **3**, 685.

THE barley for brewing purposes has improved in the province of Saxony, the best being "Chevalier" barley. Then follow barley seed, Danish barley, finally Slovacian barley. Of foreign barley, the Scotch pearl and golden melon barley are preferable. A good barley should be comparatively heavy (68·5—69·6kilos. per hectolitre). The percentage of albumen should not exceed 8·5, with 15 per cent. of water in the grain. The numbers refer to good and best barley of this year's growth. It is a fact that excellent barley is generally poor in proteïn substances. Concerning the effect of manure, the author says:—Excess of nitrogen is more harmful for barley than other cereals. Moderate quantities of Chili saltpetre have no worse effect than ammonium sulphate, nor does the quality of the barley seem to be improved by manuring with phosphates.

—A. R.

A New Method for Preventing Secondary Fermentations in the Industrial Production of Alcohol. U. Gayon and G. Dupetit. Compt. Rend. **103**, 883.

The secondary fermentations, which diminish the yield of alcohol, and also give rise to the production of a spirit of unpleasant flavour, may be entirely avoided by addition of small quantities of bismuth salts. A fermentation of a mixture of soluble maize and beet molasses, to 1 litre of which 0·1grm. bismuth nitrate had been added, gave the following results:—

	Acidity		Absolute Alcohol per litre.	Bacteria developed in the field of vision.
	At the beginning.	At the end.		
Fermentation with Bismuth	9	11	54·0cc.	0
Fermentation without Bismuth	9	33	50·3cc.	100

In distilleries at Bordeaux and Courrières, experiments were conducted on a large scale, and 0·1grm. bismuth nitrate was employed for every litre of wort. The fermentation in presence of this salt was characterised by the yeast remaining pure, and by the regularity with which the process could be carried out. The acidity was only slightly increased, and the yield of alcohol was greater.

The Turbidity of Beer due to the Formation of Starch-Dextrin, and how to prevent it. Reinke. Wochensch. f. Brauerei, **3**, 738.

Attention is drawn to the formation of starch-dextrin in beer wort, which occurs when the washing is carried on too rapidly and the diastase is destroyed through allowing hot water to run in too fast while mashing, or when the sprinkling is done at too high a temperature, etc. The starch-dextrose is hardly visible in the wort, which runs off practically clear, but may be recognised during the mashing process by its reaction with iodine: it can be removed during the actual brewing process by careful mashing, and by slowly raising the temperature of the wort in the hop-boiler. The proportion of maltose to non-maltose is generally also normal in worts with starch-dextrin, on account of the small quantity of the latter. As soon as the beer becomes richer in alcohol during fermentation, the turbidity appears, due to separation of starch-dextrin. In place of the usual remedy—viz., malt powder as such, which with the adhering dust would again introduce sporules into the beer—the author recommends a cold aqueous and filtered decoction of 1grm. malt for every 1 hectolitre of beer; even better is the addition for each hectolitre of turbid beer, of 0·03grm. pure diastase prepared according to Lintner. The saccharification, which now proceeds very rapidly, may be traced by the iodine reaction.—A. R.

On the Alcoholic Fermentation of Dextrin and Starch. U. Gayon and E. Dubourg. Compt. Rend. **103**, 885.

The alcoholic ferments (*saccharomyces*) are well known to be without action on dextrin or starch solutions, as well as on the dextrin of wort. The authors have discovered a new ferment in a specimen of mucor which possesses the double property of saccharifying both dextrin and starch and of fermenting the products; but this mucor cannot invert saccharose and convert it into alcohol. To a 10 per cent. dextrin solution some pure mucor was added on the 17th August; the fermentation proceeded regularly:—

	Reducing Sugar.		Pure Alcohol.
September 6	0·32 %	....	2·8 %
,, 14	1·67	....	4·0
October 1	2·38	....	4·2

When old beer, on which ordinary yeast no longer acts, is treated with the mucor ferment, after driving off the alcohol the fermentation begins anew, and continues until all dextrin and sugar is decomposed. A certain Bavarian beer was subjected to this fermentation on the 24th July:—

	Rotation.		Reducing Sugar.		Dextrin.		Alcohol formed.
July 24	69·5 %	..	0·96 %	..	3·16 %		—
Sept. 1	0·0	..	traces	..	traces	..	3·7 %

The same beer retained its original composition, if, after removing the alcohol, it was treated with saccharomyces. Worts gave, as was to be expected, a beer much richer in alcohol when the mucor was employed than with ordinary yeast; thus, in the former case the beer contained 6·5 per cent. alcohol, in the latter 5·2 per cent. Starch ferments less energetically than dextrin and glucose; it, however, becomes partly soluble, and alcohol is formed with evolution of carbonic acid.—A. R.

On the Reduction of Copper Sulphate during the Fermentation of Wine-Must. H. Quantin. Compt. Rend, **103**, 888.

Cuprous sulphide is the only compound of copper which is absolutely insoluble in wine-must. Copper sulphate, which has been dissolved in wine-must, separates out as sulphide. On a small scale 0·05grm. copper sulphate was converted into sulphide by 1 litre of the must. On a large scale the amount of sulphate would no doubt be larger; however, the above quantity already exceeds what would be considered necessary when treating for mildew. The reduction of copper sulphate by means of the ferments therefore suffices for eliminating all copper which may have found its way into the must. Naturally air must be excluded to prevent oxidation of the sulphide. —A. R.

On Plastering of Must. A. Andoynaud Compt. Rend. **103**, 1028.

Experienced wine-growers have found that to plaster the vintage, after putting it into the fermenting vat, not only gives it a fine colour, but also makes it keep better. The author has made comparisons, by fermenting must with and without addition of gypsum. He finds that gypsum raises the efficiency of the ferment considerably, since the plastered musts ferment more rapidly and more thoroughly. The author proved that it was really the gypsum itself and not a larger proportion of acid which caused the rapid fermentation. In consequence of this shortened process of fermentation the secondary ferments, which in a later stage are liable to change the wine, are checked in their development, with the result that the wine keeps so much better.—A. R.

Improvements in the Preparation of Grain or Cereals for Use in Brewing, Distilling, and Vinegar Making. J. Fordred, Tottenham. Eng. Pat. 4891, Nov. 8, 1884; amended April 5, 1886. 6d.

The preparation of torrefied grain—more particularly barley—to be used as a substitute for a portion of the malt employed in making mashes for the above manufactures. The torrefaction is effected in hollow cylinders revolving on hollow trunnions, and which are heated in the usual way. When the barley is sufficiently torrefied, which is known by its friable texture, its colour, smell and flavour, it is crushed by means of rollers. In some cases the grain is moistened before or during the process of torrefaction (see also this Journal, 1883, 293). —G. H. M.

Improvements relating to the Manufacture of Malt and to Apparatus therefor. H. H. Lake. From J. W. Free, Boston, U.S.A. Eng. Pat. 13,738, Oct. 26, 1886. 8d.

This is a modification of the entire process of malting, together with apparatus for carrying out the same. The chief features of the process are a building with four storeys—the steeping tank being in the third; the germination promoted by steam-heat, and when sufficiently advanced checked by cold air; a mechanical stirrer which aërates the grain and also breaks off the rootlets when they become dry; drying the malt on the floors at a low temperature and screening the grain by means of an exhaust blower.—G. H. M.

Improvements in preparing a Nutrient or Digestive and Medicinal Substance from Malt. J. Marshall, and T. A. Marshall, Govan, Lanarkshire. Eng. Pat. 13,758, Oct. 27, 1886. 4d.

The preparation of a malt flour or "ptyaloid" from malt by grinding, and separating the husks, etc., with fine sieves.—G. H. M.

(*B*) SANITARY CHEMISTRY.

Chronic Poisoning with Carbon Bisulphide. Jas. Ross, M.D., LL.D. Medical Chronicle, **5** [4], 257—269.

Two cases are reported. The first was that of a man aged twenty-four years, unmarried, and who had never suffered from any serious illness up to date of the seizure in question. He was admitted to the Manchester Infirmary, 5th May, 1886. He had commenced to work, about eight months before, in an indiarubber factory, and in this situation he was employed in the "curing-room," where he inhaled the vapours given off from the materials used there, more or less of these fumes consisting of carbon bisulphide. After working for a few weeks here, the man suffered from a burning sensation in the hands and face: these were also hot to the touch, and of a red colour. He found, however, that on putting his hands in cold water they immediately turned a livid colour, and became cold and numb, as if dead, or they looked just as if frost-bitten; in fact, he was compelled to use warm water in washing. This numbness and weakness extending gradually to his feet and legs, and being troubled with mental disturbances, he was compelled to leave work for two or three weeks, during which time he rapidly recovered. He now returned to his old work. His old symptoms soon returned, but with redoubled force, and now he soon experienced the greatest difficulty in walking, and could scarcely hold anything in his hands, which, besides being feeble, trembled a good deal, more especially when the man attempted to grasp anything. The senses of sight and hearing remained unaffected, but everything seemed to smell of the vapours of the factory he had left, and his food either seemed devoid of taste or to taste only of the loathsome vapours. The sight of food was a burden; he lost a stone in weight, and observed the wasting of his arms and legs was out of proportion to that of the rest of his body. On leaving work in the evening, he often walked like a drunken person, and talked much nonsense. The memory almost entirely failed; at night he was restless, or, if sleeping, was disturbed by horrid dreams. In the mornings he felt miserable and depressed, and even found, on return to work, some relief from again inhaling the gas—at first, at least. Sheer feebleness at length prevented this man from crawling to his work, and he was laid up for four weeks. He next got employment at a tarpaulin factory, but soon found himself unable to work, so feeble had his hands become. Not only had there been a great loss of power of the brain centres regulating memory, but those affecting important nervous functions had also much suffered; sexual appetite, for example, had been lost. He contracted colour-blindness, also, to some extent. The paralysis of principal muscular centres was, of itself and alone, such as to reduce the patient to a condition of pitiable weakness and helplessness.

The second case much resembled the first as regards the premonitory symptoms of tingling, paralysis of muscles, tremblings, livid condition of hands if dipped in cold water, loss of taste for food, of memory, and in addition the sight became affected. The man could not read, as the words all seemed, as he said, "to run together." At length he became so feeble that he could scarcely walk, and often fell down. Sexual appetite entirely failed; shooting pains along nerve courses; little sleep possible, and that disturbed by horrid dreams; violent headaches, and a longing to get back to work, where the noxious fumes brought temporary relief, and even an exaggerated feeling of pleasure. This soon gave way to a feeling of intense apathy and wretchedness. These cases were not exceptional ones, for this man was not affected, he declared, so much as some of his fellow-workmen. He stated that some of these, under the effects of the gas, became very talkative, and often talked a great deal of nonsense. One man, *e.g.*, coming to work in the morning, declared he was in Liverpool the night before, a statement that could not possibly have been true. Another workman, apparently eager to escape from some imaginary danger, jumped through a window, ran across an open court, and having crept under a joiner's bench, tried to hide by covering himself with shavings. One or two of the workmen had gone quite mad, and had been sent to the lunatic asylum. The colour-vision of the patient here considered was defective; purple he called white, and could not distinguish red from blue.

Dr. Ross states that these cases of paralysis from the inhalation of carbon bisulphide show that such paralysis belongs to the group which is caused by various toxic agents, such as alcohol, lead, arsenic, and certain animal poisons like that of diphtheria. This paralysis, in fact, resembles alcoholic paralysis more nearly than it does any other form of multiple neuritis. Sometimes symptoms are found closely resembling those of delirium tremens, as in the case of the workman jumping through the window to hide himself in a joiner's shop. The statements and cases are well authenticated, and neither alcohol nor lead played any part whatever in the cases of these two patients, as causes or adjuncts in the paralysis observed.

Dr. Ross concludes:—"If it be true, then, that we have in our midst certain workshops in which the process of manufacture is so deleterious to the health of the workmen that a certain proportion of them is reduced in a few months to the pitiable condition of paralytic helplessness manifested by these two unfortunate men, it is hardly necessary for me to maintain, in the face of all recent factory legislation, that these workshops ought to be placed under the most stringent regulations, and be subject to the frequent visits of a Government inspector."—W. S.

XVIII.—ELECTRO-CHEMISTRY.

Improvements in Voltaic Batteries. D. G. FitzGerald, London. Eng. Pat. 335, Jan. 8, 1886. 8d.

THE inventor proposes a new peroxide plate, formed from oxide of lead and glycerine, admixed with water or with suitable saline or acid solutions. He also proposes a compound plate, having a core made in the above way, surrounded by one of the more porous oxide of lead compositions mentioned in Eng. Pat. 4671, 1885. Contact is made with the plate by platinum strips attached to a piece of ebonite, and so arranged as to make contact both with the core and the outer composition. The part of a peroxide plate at which contact is to be made may be coated with plumbago, which fills the pores and makes the contact more perfect.—E. T.

A Secondary Voltaic Battery. O. Imray, London. Eng. Pat. 611, Jan. 14, 1886. 8d.

THIS secondary cell consists of a shallow leaden trough, suitably insulated in a wooden frame, in which are placed ebonite troughs parallel to each other. These troughs contain leaden frames (the lead may be alloyed with a little tin or other white metal) on the upper side of which are numerous grooves, divided by partitions, having lips projecting over the grooves to retain the material packed in the grooves. The material consists of spongy lead or peroxide of lead mixed with metallic lead. The insulated frames united together form one electrode, while the leaden trough constitutes the other. The spaces between the ebonite troughs may be filled with frames similar to those in the troughs.—E. T.

An Improved Construction or Formation of Plates with Composition for Electric Batteries. J. H. Noad, Upton, and R. Matthews, London. Eng. Pat. 1054, Jan. 23, 1886. 4d.

ACCORDING to this method, plates of woven wire, serving as one of the poles of a battery, are coated with a compound consisting of litharge formed into a paste with glycerine. The plates thus formed are baked in an oven at a temperature of about 300° F. to oxidise the glycerine. —B. T.

Improved Construction of Secondary or Storage Batteries. G. E. Dorman, Stafford. Eng. Pat. 1610, Feb. 4, 1886. 8d.

THESE secondary batteries are formed of lead strips piled one above another, but separated from each other by wooden or vulcanised strips, and by pads or cushions of a permeable material such as glass-wool, the alternate strips being connected together in the usual way. —B. T.

XIX.—PAPER, PASTEBOARD, Etc.

Improvements in extracting Moisture from Pulp produced from Wood or other Fibrous Materials. J. T. and J. M'Dougall, Manchester. Eng Pat. 1795, Feb. 6, 1886. 6d.

IT is proposed to reduce the proportion of water usually found in well-pressed wood-pulp—generally about 60 per cent.—by pressing the pulp in bags or wrappers, and by which means it is claimed a larger proportion of moisture will be removed than has been hitherto the case.—H. A. R.

XX.—FINE CHEMICALS, ALKALOIDS, ESSENCES AND EXTRACTS.

On Dextro-Hexyl Alcohol from Roman Oil of Camomile. P. v. Romburgh. Rec. des Trav. Chim. des Pays-Bas. **5**, 219.

Two kilos. of oil of camomile were saponified, and the alcohols thus produced separated by fractional distillation. 80grms. of Köbig's hexyl alcohol were obtained, the specific gravity of which was 0·829 at 15° C. It boiled at 154°, and turned the plane of polarisation to the right —$\alpha_d = +8·2°$. On oxidising by means of chromic acid, the alcohol yielded caproic acid, $C_6H_{12}O_2$, a colourless liquid of unpleasant smell, boiling at 196—198°, and also turning polarised light to the right—$\alpha_d = +48·92°$. The amido-derivative of this acid crystallised in long needles, fusing at 124° C. The author believes that this hexyl alcohol is ββ-methylethylpropyl alcohol, $(CH_3)(C_2H_5)CH—CH_2—CH_2OH$, and its acid is ββ-methylethylpropionic acid, $(CH_3)(C_2H_5)CH—CH_2—COOH$. —S. H.

Hipe Nuts from the Cameroons. Chem. Zeit. **10**, 1528.

THIS drug consists of the cotyledons of the seeds of *Vateria indica L.*, which belongs to the class of *Dipterocarpeæ*. The plant has been known for a long time, and is extensively used in India for extracting the oil it contains. The seed, like so many other drugs containing tannin, is used as a remedy against colic. It is worth noticing that the tannin contained in these seeds becomes yellow on addition of potash, and the colour changes to a bluish-green on warming.—A. R.

On Cinchonine. W. J. Comstock and W. Koenigs. Ber. **19**, 2853—2859.

CINCHONINE combines with 1mol. of bromine to form a di-bromide, $C_{19}H_{22}N_2OBr_2$, which on boiling with alcoholic KOH loses 2HBr, and is converted into *dehydrocinchonine*, $C_{19}H_{20}N_2O$. When the latter base is treated with PCl_5 it yields *dehydrocinchonine chloride*, $C_{19}H_{19}N_2Cl$, which by boiling with alcoholic KOH is converted into *dehydrocinchene*, $C_{19}H_{18}N_2$. Dehydrocinchene can also be obtained from cinchonine by conversion into cinchene, and heating the di-bromide of the latter with alcoholic KOH.

Cinchonine dibromide, $C_{19}H_{22}N_2OBr_2 + H_2O$, was earlier mistaken for di-bromo-cinchonine, and described under that name. With cold concentrated H_2SO_4 it forms an ethereal sulphate, sparingly soluble in cold water.

Dehydrocinchonine, $C_{19}H_{20}N_2O$, crystallises from dilute alcohol in colourless needles, which melt at 202—203°, and can be sublimed. It is easily soluble in alcohol, acetone, ether, and benzene, scarcely soluble in water or petroleum spirit. The hydrobromide, $C_{19}H_{20}N_2O,HBr_2$, forms colourless prisms, and the hydrochloride, $C_{19}H_{20}N_2O,HCl$, long silky needles.

Dehydrocinchonine chloride, $C_{19}H_{19}N_2Cl$, is derived from the dehydrocinchonine by the replacement of OH by Cl. It is very soluble in benzene, alcohol, and ether, but is insoluble in petroleum spirit. It crystallises from benzene on addition of petroleum spirit, and melts at 148—149°.

Cinchene di-bromide, $C_{19}H_{20}N_2Br_2$, is obtained by the addition of bromine to a cold solution of cinchene in chloroform. It forms colourless crystals, which melt at 110—113°. The hydrobromide crystallises in colourless needles, sparingly soluble in cold water. The nitrate and zinc-double chloride are also well crystallised salts, sparingly soluble in cold, readily in hot water.

Dehydrocinchene, $C_{19}H_{18}N_2$, crystallises from dilute alcohol in long colourless needles (+3H_2O), which melt at about 60°. The hydrobromide, $C_{19}H_{18}N_2,H_2Br_2$, forms small prisms, very soluble in water, but sparingly in absolute alcohol. The platino-chloride, $C_{19}H_{18}N_2,H_2PtCl_6$, forms slightly soluble red tables. The acid tartrate is sparingly soluble in cold water.

—A. G. G.

Method for the Preparation of Lanolin and Anhydrous Lanolin from the Waste Liquors of Wool-washing Establishments, and from Commercial Wool Fat. C. D. Abel, London. Eng. Pat. 326, Jan. 8, 1886. 6d.

LANOLIN was first described in Eng. Pat. 4992, Oct. 22, 1882. For the process of its purification there described, treatment of the raw lanolin with acetone is now substituted. This dissolves out the pure fat, leaving the soaps, etc., undissolved, and the solvent may be recovered by distillation. According to another method, the crude mass may be treated with benzene, carbon disulphide, etc., when both soaps and fat are dissolved, and impurities left behind; from this, the addition of acetone precipitates the soaps, etc., leaving pure wool-fat in solution. Prior to treatment with solvents, the commercial wool-fat may be melted and heated with alkalis, alkaline earths or their hydrates, or even with oxides of heavy metals.—W. L. C.

An Improved Process and Apparatus for the Purification of Alcohol. J. A. F. Bang and M. C. A. Ruffin, Paris Eng. Pat. 783, Jan. 18, 1886. 8d.

AN improvement of Eng. Pat. 10,870, 1884. Heavy hydrocarbons boiling above 100° C. are used in place of the light petroleum spirit of the former specification; the hydrocarbons are also purified by means of strong rectified spirit instead of sulphuric acid. The apparatus used is also modified in such a way that a larger surface of hydrocarbon is exposed to the action of the alcoholic distillate, a vertical chamber divided into compartments by perforated diaphragms being used instead of separate vessels.—G. H. M.

XXII.—GENERAL ANALYTICAL CHEMISTRY.

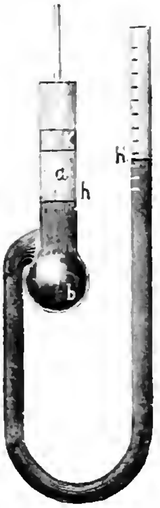
Arrangement for Combining the Operations of Heating with Reflux Condenser, and afterwards Distilling. Dr. H. Michaelis. Chem. Zeit. **10**, 1556.

THE author describes an apparatus very similar to Lintner's for simplifying this operation. The arrangement will be readily understood from a glance at the figure. The inner tube of the Liebig condenser is bent at right angles, and passes in a slanting direction through the cork.

—A. R.

Apparatus for Determining the Specific Gravity of Solids and Liquids. P. Raikow and N. Prodonaw. Chem. Zeit. **10**, 1556.

THE apparatus consists of a bent tube $a\,a^1$, the right limb of which is drawn out and provided with a cc. scale. The left limb is wider, and at b a bladder-shaped bulb is blown. Water being poured into the tube, owing to capiliary action, the heights h, h^1, to which the water rises in the two limbs, will differ. The difference being noted, the body, whose sp. gr. is to be determined, is brought into b. Part of the water is expelled, and the level of the water in both limbs is thus raised. On now compressing the air over the liquid by means of a piston k, until the original level of the fluid is again reached, the volume of water which is present over the original mark in the right limb will at once give the volume of the immersed body, whence the sp. gr. is calculated.



In determining the sp. gr. of a liquid, some fluid with which it does not mix is first brought into the tube, the heights in the two limbs noted, and the tube and fluid then weighed. Some of the liquid, whose sp. gr. is to be found, is now introduced into the left limb, the level of the fluid in a restored in the manner previously described, and the increase in volume in a^1 noted. If the tube be weighed with the two liquids, the weight of liquid last introduced is found, whence by division with its volume the sp. gr. is determined. The apparatus is said to be useful for determinations of sp. gr., where only small quantities of the liquid are at disposal.—A. R.

The Electrolytic Evolution of Arseniuretted Hydrogen for the Detection of Arsenic. C. H. Wolff, Pharm. Centr. Halle, **7**, 608.

THE author has designed a special apparatus for the detection of arsenic by the electrolytic evolution of hydrogen arsenide, which is decomposed into arsenic, thus producing the well-known arsenic mirrors. In this manner, even 0·00001gr. arsenic trioxide can be detected. With an equal strength of the electric current, the arsenic mirrors always show an equal intensity, and by comparing the mirrors obtained from known quantities of arsenic, the smallest amount may be estimated.

—S. H.

Volumetric Estimation of Zinc in Zinc-dust. F. Weil. Compt. Rend. **103**, 1013.

A COPPER SOLUTION is prepared by dissolving 12·519grms. of pure cupric oxide in a slight excess of hydrochloric acid and diluting to 1 litre, 10cc. of which contain 0·1grm. Cu. 50cc. of this solution are treated in a porcelain dish with ammonia until a slight permanent turbidity appears, but the liquid must still be slightly acid. 0·4grm. of the zinc-dust to be tested is now added, and the mass stirred from time to time with a platinum wire, until the wire no longer becomes covered with a black or red skin. The precipitation of the copper by zinc in a porcelain dish takes about one hour, whereas it can be completed in a platinum dish in ten minutes. A drop of acetic acid is added to clarify the solution, which is decanted, and after adding the washings of the copper precipitate, made up to 100 or 200cc. 10cc. of the washings are run into a flask to which from 20 to 30cc. of hydrochloric acid are added and the whole is boiled. The copper still in solution is then titrated back with a stannous chloride solution, 10cc. of which are equal to 0·04grm. Cu. By subtracting the copper thus found from the 0·5grm. Cu employed for the test, the quantity of copper is obtained which was precipitated by the zinc, and by multiplying this figure with the factor 1·0236 the quantity of zinc in 0·4grm. zinc-dust is found.—S. H.

Examination of Castor Oil for other Fat Oils. Finkener.

Chem. Zeit. **10**, 1500.

If pure castor oil be treated with concentrated sulphuric acid, a product is obtained which dissolves almost completely in forty parts of water, whereas other fat oils, such as sesame or olive oil, treated in the same manner, yield no clear solution, but an emulsion. If castor oil be mixed with one-fifth of sesame or olive oil, sulphuric acid does not detect the presence of the two latter oils, as the mixture gives sulphonic acids, which are soluble in water. But it was found that alcohol of a specific gravity of 0·829 dissolves at 17·5° C. castor oil in nearly any proportion, whereas other fat oils are only slightly soluble in the same reagent. The test is performed in glass cylinders of 100cc. capacity and 25mm. diameter, which have marks for 10cc. and 60cc., measured from the bottom. 10cc. of the oil to be tested are put into the cylinder, 50cc. alcohol added, and, after inserting the stopper, shaken, and then allowed to stand for two to three minutes. A strong turbidity, which does not disappear even at 20° C., shows that the oil was not pure castor oil, but contained at least more than ten per cent. of other oils.—S. H.

On the Determination of Sulphur in Albuminoïds. W. Kochs.

Chem. Centr. **17**, 894.

According to the author, it is the amount of sulphur in albuminoïd which decides whether it belongs to the albuminoïds proper or to the glutens. Furthermore, it is stated that one may calculate approximately the quantity of glutinous- and of albuminoïd-peptone in a mixture of albuminoïds, such as peptone preparations, when the amount of sulphur contained in the latter is known. The reason the numbers previously given by the author differ from those of Fresenius is due to the fact, that Carius' method is not well applicable to albuminoïds, since at the temperature employed all the sulphur is not converted into sulphuric acid. Whether the temperature is kept for two hours at 120°, or three hours at 200°, is immaterial to the final result. On heating higher, explosions generally occurred. Good results were, however, obtained with Liebig's method for determining sulphur. It may be assumed that muscular albumen contains from 1—1·2 per cent. sulphur, but that muscular gluten is quite free from sulphur. For certain bodies, particularly albuminoïds free from ash, Liebig's method is not practicable, owing to the violent evolution of gas. Such bodies are first evaporated with ten times their weight of nitric acid (sp. gr. 1·4) on the water bath, and the residue is melted in a silver crucible with caustic potash and a little saltpetre.—A. R.

On the Examination and Colorimetric Determination of Salicylic Acid. Frehse.

Journ. Pharm. Chem. **14**, 507.

The following precautions are necessary in order to obtain good results in the determination of salicylic acid by means of ferric chloride:—1. The standard solution which serves for comparison must frequently be renewed, since dilute solutions of salicylic acid and also its sodium salt are gradually decomposed. (A solution of 0·05grm. salicylic acid in 1 litre gave no colouration with ferric chloride after five months.) 2. The salicylic acid must first be extracted with ether, and no coloured solutions should be directly examined, for many bodies weaken the colour reaction or suppress it entirely, such as acids, alkalis, neutral salts—viz., phosphates, tartrates, oxalates, etc. 3. The ferric chloride solution must be very dilute, for with small quantities of salicylic acid a slight excess of ferric chloride destroys the colouration.—A. R.

Contribution to the Assay of Opium. E. Dieterich.

Pharm. C.-H. N. F. **7**, 529, 541.

Knowing that all processes in common use for testing opium give unreliable results, the author has examined the method employed by Flückiger with a view to its perfection. The chief objections to this process are:—The addition of alcohol hinders the precipitation of the morphia, and, on the other hand, promotes the separation of calcium salts. The deposition of the alkaloid is influenced by the duration and intensity of the shaking (*Chem. Zeit.* **10**, 1224). And finally, the author finds that on adding the ammonia slowly a flocculent precipitate of narcotine at first separates (the whole of this body being separable by accurate neutralisation), and is afterwards masked by the crystalline morphia precipitate. He therefore recommends the adoption of the following methods, which are expeditious and accurate:—

For Opium Powder.—6grms. of the dried substance are extracted with 60grms. of water with occasional shaking during 12 hours. After filtration 2cc. of normal ammonia are added to 50grms. of the solution, and the narcotine is removed by passing through a 10cm. filter. 44·4grms. of this second filtrate (=4grms. opium) are then mixed in a weighed Erlenmeyer's flask with 10grms. of ether and thoroughly shaken for one minute, then with 4cc. of normal ammonia, and again shaken; after standing for six hours the ether layer is poured off through an 8cm. filter, a further quantity of 10grms. of ether is then agitated with the liquid, and after separation filtered, and finally the aqueous solution is passed through the same filter, the crystals clinging to the walls of the glass vessel being disregarded. The flask and filter are each washed twice with 5cc. of ether-saturated water and dried at 100° C. The crystals of morphine may then be transferred without loss by means of a camel-hair brush from the filter to the flask, where they are heated at 100° until the weight is constant.

For Opium Extract.—3grms. are dissolved in 42grms. of water, and after one hour treated with 2cc. of ammonia and filtered as above; 31·7grms. of the filtrate (=2grms. extract) are then used for the subsequent stages of the process, which are conducted as in the case of the powder.

For Opium Tincture.—50grms. are evaporated to one half their bulk; the original volume is made up with distilled water, and the assay completed as already described, 44·4grms. (=4grms. tincture) of the filtrate from the narcotine being employed.—W. G. M.

Pure Butter and Artificial Butter. Professor Scheffer.

Pharm. Rundsch. **4**, 248.

Pure butter differs from artificial butter by containing very little or no stearine. The author has based on this fact an easy method for distinguishing between the two. He prepares a solution, which is a mixture of 40 parts by volume of rectified fusel-oil, and 60 parts by volume of ether (sp. gr. 0·725). 1grm. of pure butter dissolves in 3cc. of this mixture at 26—28° to a clear solution; the same weight of beef-suet requires 50cc. for complete solution, 1grm. lard 16cc., and 1grm. stearin as much as 550cc. of the solvent. In examining samples 0·5 to 1grm. of fat is introduced into a 12cc. test tube, 3cc. of the solvent are added, and the well-corked test tube heated in a water bath with frequent shaking from about 18° to 28°, and kept at 28° for some time. Pure butter dissolves to a clear fluid; if the contents of the test tube are not clear, more of the solvent is introduced from a burette, until all is dissolved. The greater the quantity of the solvent required for complete solution the greater is the adulteration of the butter. As is apparent from the following numbers, it is possible to estimate approximately the extent of the adulteration. Thus:—1grm. pure butter required 3cc.; 0·1grm. lard and 0·9grm. butter, 3·9cc.; 0·2grm. lard and 0·8grm. butter, 4·8cc.; 0·3grm. lard and 0·7grm. butter, 5·7cc.; 0·4grm. lard and 0·6grm. butter, 6·5cc.; 0·9grm. lard and 0·1grm. butter, 14·4cc.—A. R.

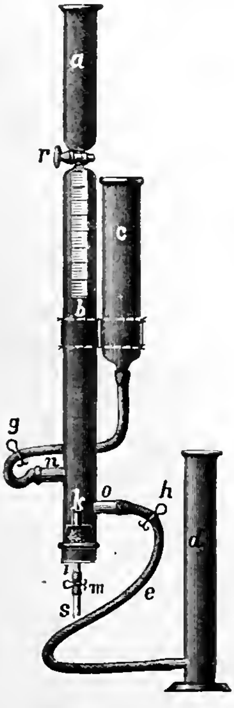
The Colour Reaction given by Morphine with Sulphuric Acid. Gasselin and Lévy. Pharm. Chim. **14**, 458.

According to Donath (this Journal, 1886, 618) morphine gives a colour reaction with sulphuric acid in presence of potassium arsenate. The authors find that the latter has nothing to do with the reaction, as the colouration is just as intense with pure sulphuric acid. Presence of various salts, such as phosphates, does not interfere with the reaction. As Jorissen has already pointed out, pure codeïne gives a similar colouration, but less intense.
—A. R.

New Apparatus for the Determination of Urea. G. Frutiger. Bull. Soc. Chim. [2], **46**, 611.

The lower end of the burette *b* is provided with two short side tubes, *o* and *n*; a stout piece of caoutchouc tubing connects *o* with the cylinder *d*, which is filled with mercury, and *n* similarly communicates with the tube *c*. This latter is fastened to *b* by means of brass wire. The lower end of the burette is furnished with a caoutchouc stopper, and through it passes the tube *k*·*l*, which reaches to the level of the side tube *o*, and is closed below by a stop-cock *m*.

In order to use the apparatus, water is poured into *c*, and a portion of it allowed to flow into the burette. *g* is now closed and *m* opened, so that the water passes out of the burette, care being taken that *k s* remains full of water, and that no air-bubbles can enter. The apparatus is then complete for use for any number of determinations. By raising *d*, the burette and a portion of *a* are now filled with mercury; stop-cock *r* is now closed and *d* again lowered. Should there be a film of water on the mercury in *a* it must be removed. 1cc. urine is now introduced into *a*, and, having opened *r*, is allowed to flow into the burette. After washing down with a little water, sodium hypobromite is introduced into *a*, and from thence passed into the burette, when the stop-cock is quickly turned off. The gas is set free, and some mercury is expelled into *d*. After the evolution of gas has ceased, the mercury still contained in the burette is removed by pouring water into *a* and slowly opening stop-cock *r*. When the mercury has reached the level *o*, the water containing hypobromite is expelled by again passing water from *a* through *r*, and opening *m* slowly. To prevent any air from entering, there must always be some water in *a*. For measuring the volume of gas, *r* and *m* are closed; *g* is then opened, and the level of the fluids in *b* and *c* adjusted by adding or removing water from *c*. The analysis is complete in a few minutes. About a pound of mercury is required.—A. R.



Examination of Different Extracts. Schweissinger. Pharm. Centr. Halle, **7**, 597 and 613.

Extractum Graminis.—Both the dry root and the extract contain mannite, fructose, dextrin, lactates, and triticin, a substance related to inulin. The aqueous solution of triticin turns the plane of polarisation to the left, upon which reaction an adulteration of the extract with dextrogyrate substances can be based. A 10 per cent. solution of the genuine extract polarised $a_d = -5·3°$; after inversion, $a_d = -7°$.

Extractum Trifolii. — The vegetable bitter can be easily separated by digestion with animal charcoal. 20grms. of extr. trif. dissolved in 150cc. of water and digested for two days with 10grms. of freshly-calcined charcoal are completely deprived of any bitter principle. By boiling the charcoal with alcohol, the vegetable bitter is dissolved, and remains behind after driving off the alcohol.

Extractum Colombo.—A few grains dissolved in water acidified with sulphuric acid form a clear solution of lemon-yellow colour. Chlorine water turns the solution red, which finally becomes colourless.

Extractum Hydrastis canadensis. — The solution of this extract gives the same colour reaction as that of extr. col., and this may be accounted for by the presence of berberine in both extracts. One drop of the liquid extract dissolved in 1cc. of water turns red with two drops of fuming nitric acid.

Extractum Ligni Campechianii.—Logwood extract is frequently adulterated with molasses or dextrine. Since a pure extract contains no substances which act on polarised light or Fehling's solution, these adulterations can be easily detected by precipitating the liquid extract with lead acetate and examining the filtrate.—S. H.

Remarks on Molisch's New Reactions for Sugar. Lenken. Apoth. Zeit. **1**, 246.

Molisch's reactions (*Chem Zeit.* **10**, 620) consist in the production of a violet or red colour by the action of sulphuric acid on α-naphthol or thymol in the presence of sugar. Normal urine treated in this manner turns violet or red, and Molisch therefrom concluded that normal urine contains sugar. Leuken closely examined these reactions, and showed that the colour obtained with grape-sugar is different from that obtained with urine, if the process be slightly modified. Sugar and the glycosides generally show similar colour reactions with a large number of aromatic compounds—menthol, for instance, giving more distinct colours than α-naphthol or thymol. Besides sugar, all those compounds which split off sugar by the action of sulphuric acid, such as amygdalin, salicin, piperin, cumarin, etc., give a violet-red colour with menthol and sulphuric acid. Alkaloids do not show this peculiarity, and this reaction is therefore suitable for the examination of alkaloids for sugar and glycosides. The author also showed that thymol and sulphuric acid produce a red colour with different compounds which are normal constituents of urine, and the red colour caused by thymol and sulphuric acid is therefore no proof of the presence of sugar in urine.
—S. H.

Notes on New Sugar Reactions. T. Seegen. Centralblatt. Med. Wiss. 1886, 44.

SOLUTIONS of peptone, pure egg-albumen, serum-albumen, and casein mixed with a solution of *α* naphthol or thymol give on addition of concentrated sulphuric acid in excess the same reaction, which Molisch has recently described as a reaction characteristic of sugar and other carbohydrates. Possibly the albuminoïds are decomposed by the sulphuric acid with formation of sugar. At all events, Molisch's reaction has lost value, and certain conclusions drawn from it have therefore become untenable—such, *e.g.*, as the assertion that "normal urine unquestionably contains sugar."—A. R.

Modifications of Kjeldahl's Method of Estimating Nitrogen. C. Arnold. Arch. d. Pharm. 1886, 792.

THE author recommends the following alterations:—

1. The flask in which the substance is heated with sulphuric acid is closed by a test-tube, the middle of which is expanded into a bulb in order to avoid loss by spirting (Fig. 1). This form of stopper is to be preferred to the tapering pear-shaped one, for it is less liable to be blown out by the bumping of the liquid, and as the condensed dilute sulphuric acid does not drop so readily from it into the hot liquid below, spirting is to a great extent avoided.

2. In the distillation of the ammonia, caustic soda may be carried over into the receiver, and many forms of apparatus have been devised to prevent this. The author recommends that of Dr. Müncke (Fig. 2). Pure caustic soda and zinc may be heated in it for hours, and even when frothing, bumping, or spirting occurs, no caustic is carried over. Attention must be paid to the following points: Caustic soda, when not purified by solution in alcohol frequently contains nitrites, which yield ammonia when heated with zinc. If mercury is employed, potassium sulphide must be added to the caustic alkali in order to decompose mercury-ammonium compounds. For 1grm. of mercury 10cc. of a 20 per cent. solution of potassium sulphide are required. The sulphide must be tested for nitrites and nitrates.

FIG. 1.

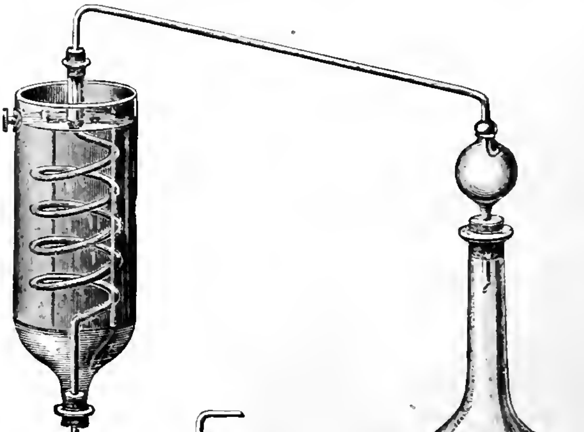


FIG. 2.

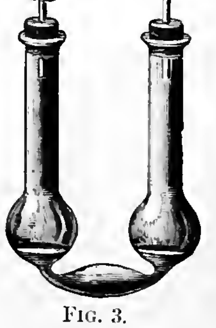

FIG. 3.

3. The ammonia is best collected in a Peligot's tube (Fig. 3). With this apparatus it is easy to ascertain whether the joints are air-tight, and the titration may be carried out in the tube itself.

4. The author employs $\frac{1}{5}$ normal solutions of hydrochloric or sulphuric acid and $\frac{1}{5}$ normal solution of ammonia, and recommends fluorescein as the best indicator. Neither organic acids nor fixed alkalis should be employed in the titration. With a black glass plate placed below the Peligot's tube, the fluorescence becomes quite visible on addition of a single drop even of $\frac{1}{5}$ normal ammonia solution, after the acid has been neutralised. The dilute solution of ammonia does not absorb carbon dioxide from the air, and complicated apparatus for the protection of the liquid is therefore unnecessary.—S. Y.

Notes on the Testing of Quinine. E. de Vrij. Nieuw. Tijdsch. v. d. Pharm. in Nederland, **2**, 365.

WHEN 4grms. of quinine sulphate are dissolved in 400grms. of boiling water, 1grm. of potassium chromate dissolved in a little water added, and the liquid put aside for several hours, quinine chromate is deposited in crystals, which are anhydrous, and have the composition $(C_{20}H_{24}N_2O_2)_2H_2CrO_4$. One part of this salt dissolves in 2733 parts of water at 14° C. For testing quinine for cinchonidine, 5grms. quinine sulphate are dissolved in 500grms. of boiling water, 1·2grm. potassium chromate dissolved in a little water added, and the liquid allowed to stand until the next day. The crystals of quinine chromate are then filtered and washed. The filtrate is warmed on the water-bath with sodium hydrate for some time, whereby the cinchonidine is precipitated, which is filtered, dried, and weighed. For determining quantitatively the amount of pure quinine in quinine sulphate, 2grms. of the latter are dissolved in 200grms. of boiling water and treated with 0·5grm. of potassium chromate, as previously described. The crystals are filtered, washed, dried, and weighed, and for every 100cc. of the filtrate 0·05grm. quinine chromate is added to allow for the slight solubility of quinine chromate. From the latter the amount of quinine can be directly calculated.
—S. H.

A New Reaction of Thymol. R. Stoermer. Pharm. Zeit. **31**, 744.

If thymol be dissolved in concentrated potassium hydrate solution, and the liquid slightly warmed, on adding a few drops of chloroform a violet colour is at once produced, which on shaking turns reddish violet. 0·01gr. thymol can be thus detected. The liquid soon separates in different layers: the lowest (chloroform) is red, the middle (potash lye) is scarcely coloured, and the top one (thymol) is dark violet.—S. H.

A New Reaction of Tannic Acid. J. E. Saul. Pharm. J. Trans. **3**, 387.

A USEFUL METHOD for distinguishing gallic acid from tannic acid is the following: 0·01gr. of tannin is shaken with 3cc. of water. Three drops of an alcoholic thymol solution and 3cc. of concentrated sulphuric acid are added. Pure tannin produces a turbid pink solution, whereas gallic acid remains colourless. Pyrogallol gives a dark violet solution.—S. H.

The Applicability of Nitroso-β-Naphthol for the Estimation of Ferric Oxide in the Presence of Alumina. Em. Breutel. Ber. österr. Ges. z. Förd. d. Ind. **8**, 129.

Ferric salts are completely precipitated by nitroso-β-naphthol, ferrous salts but slowly and incompletely. In a mixture of the two oxides, both the oxide and the protoxide are completely precipitated. The process is especially useful in the analysis of clay, which contains but little iron, and for the estimation of iron in aluminium sulphate. If so little iron is present that nitroso-β-naphthol only produces a very slight precipitate, the author determines the iron in the cold solution colourimetrically by means of potassium ferrocyanide. —S. H.

Method of and Apparatus for Determining the Quantity of Fat in Milk. C. G. P. De Laval, Stockholm. Eng. Pat. 8610, July 16, 1885. 8d.

The milk is warmed with an equal volume of acetic acid, containing one volume in twenty of sulphuric acid. It is then introduced into a fine glass tube, open at both ends, which is subjected to very rapid rotation in a centrifugal machine. The fine glass tube is graduated, and in this part the fat collects, so that its percentage can be easily read off. Twelve tests can be made simultaneously in ten minutes, or seventy-two tests per hour by the apparatus, which is described and figured. The speed of revolution is 6000 per minute. It is claimed that the results are accurate to within 0·5 per cent. of the total fat present, or within 0·02 per cent. on the milk.—W. L. C.

Determinations of Fat in Milk. M. Kretzschmar. Chem. Zeit. **10**, 1556.

The hard mass resulting from evaporating milk, etc., in which the fat is to be determined, with gypsum, is only with difficulty entirely removed out of the dish. The author proposes the following improvement:—A ball of cotton wool is made, the half of which must be somewhat larger than the interior of the evaporating dish. A square piece of tinfoil, about 14·8cm. in length (its thickness should be such that it weighs about 2·4 grms.), is placed on the dish (diameter for 20cc. of liquid about 8·7cm.), the foil firmly pressed into the dish by the aid of the cotton-wool ball, and fixed by turning its edges downwards over the edge of the dish. Gypsum is now spread over the foil, and the milk, etc., introduced. The milk can be readily evaporated without stirring. The whole mass, including the tinfoil, is then lifted out of the dish and pulverised. The tinfoil is cut up and extracted together with the powder.—A. R.

New Books.

Chemiker-Kalendar, 1887. Ein Hulfsbuch fur Chemiker, Physiker, Mineralogen, Industrielle, Pharmaceuten, Huttenmanner, u.s.w. Von Dr. Rudolf Biedermann. Achter Jahrgang. Mit einer Beilage. Berlin: 1887. Verlag von Julius Springer. London: H. Grevel & Co., 33, King Street, Covent Garden.

Small 8vo volume in pocket-book form, containing Calendar and table of frequently-used Atomic Weights in the cover, Title-page, Preface and Table of Contents; also Diary, followed by 28 blank pages for the record of notes, etc. Then follows a most complete set of data in tabulated form, supplying almost every imaginable need of the Chemist that can be supplied by such means, and the work closes with a few pages ruled for the recording of names and addresses, fly-leaves at the end supplying the German Post-office Regulations, and a complete Railway Map of the German Empire. The text covers 289 pages. A small paper-covered volume, forming an Appendix to the Kalendar, and termed the "Beilage zum Chemiker-Kalender, 1887," supplies also, in tabular arrangement, the wants of the Physicist, in giving all the more commonly required physical constants and other data, and closes with an Appendix specially interesting to students desirous of gaining information as to the Professors and Docenten in the various German Polytechnic Schools and Universities, and to the subjects taught in those institutions. Not even the limited means of the poorer classes of students are forgotten, and a tabulated list is given of the prices of the various sizes of the more important articles of chemical apparatus.

Trade Report.

France.

Duty on Paper Pastes.

The following decision, affecting the classification of paper pastes in the French Customs Tariff, has recently been given by the French Direction of Customs:—

Under the tariff, ordinary pasteboard at present pays the same duty as paper paste pressed and pasteboard simply moulded made of wood or straw paste, and imported in the shape of leaves moist or not. They are only admitted duty free when the sheets are torn so as to be absolutely useless except for the manufacture of paper, or again, when the importers consent to place them under the transit regulations. The greater part of the imported pastes are imported under these conditions.

Switzerland.

Classification of Articles in Customs Tariff.

(*Note.*—Quintal = 220·4lb. avoirdupois. Franc = 9½d).

Parts of apparatus for glass blowing, plates (frames) of lead perforated, for electric batteries—category, 105; duty, 4 francs per quintal.

So-called cobalt (artificial)—category, 159; duty, 5 francs per quintal.

Russia.

Classification of Articles in Customs Tariff.

(*Note.*—Poud = 36lb. avoirdupois. Funt = 0·902lb. avoirdupois Square arshine = 5·44 square feet. Gold rouble = 3s. 2d.)

The following decisions affecting the classification of articles in the Russian Customs Tariff have recently been given by the Russian Government:—

The following homœopathic medicines—ailanthus, buso, cannabis sativa, cedron, chamomilla, cyclamen, cynophalium polycephalum, lachesis, lactucin, pyrocarbon, symphytum racemosum, tarantula, viola odorata, and zincum—are to be included under Section 151, and to pay a duty of 10 roubles per poud gross, with an addition of 20 per cent. on each rouble of duty leviable.

The liquid "carbolineum avenarius," for soaking wood, Section 16, duty 5 copecks per poud gross, with an addition of 20 per cent. on each rouble of duty leviable.

Alloys of zinc and antimony, Section 124, duty 22 copecks per poud.

Italy.

Classification of Articles in Customs Tariff.

(*Note.*—Hectogramme = 3·215oz. troy. Kilogramme = 2·204lb. avoirdupois. Quintal = 220·4lb. avoirdupois. Lira = 9½d.)

The following decisions, affecting the classification of various articles which have been the subject of disputes, have recently been given by the Italian Customs authorities.

Sulphur of zinc mixed with sulphate of barytes to be included in Category III., No. 33 (oxide of iron, lead, pewter, and zinc), duty 2 lire per quintal.

Articles composed of wine, extract of meat, malt, etc., Category III., No. 56 (medicinal articles compounded, not distinguished), 120 lire per quintal.

Vermilion, dry, with the addition of aniline colour. Category IV., No. 64*a* (colours, etc., derived from tar in a dry state), 15 lire per quintal.

Extract of dyewoods. Category IV., No. 65 (colouring extracts of wood and all other dyeing stuffs), 12 lire 50 per quintal.

UNITED STATES.

Classification of Articles in Customs Tariff.

An article called "toluidine," known in commerce as a heavy aniline oil, a manufactured article, and a product of coal-tar (not a colour), is dutiable at the rate of 20 per cent. *ad valorem*, under provision 81 in Schedule A, as products of coal-tar.

Alizarin blue and gallein, which are coal-tar colours, are dutiable at the rate of 35 per cent *ad valorem*, under the provisions of Section 82, as "all coal-tar colours or dyes, by whatever name known."

Sulphate of antimony, which consists of an artificially-produced chemical compound well known as "golden sulphuret of antimony," or "pentasulphide of antimony," is dutiable at the rate of 25 per cent. *ad valorem*, under the provision in Section 92 for "all chemical compounds," etc.

Cocoa butter, which consists of an unctuous, fatty body, or concrete oil, derived by expression and heat from the seeds of the "Theobroma cacao," and which is in fact an oil expressed or rendered from such seeds, is held to be dutiable at the rate of 25 per cent. *ad valorem*, under the provision in Section 92 for "all preparations known as essential oils, expressed oils, distilled oils, rendered oils, by whatever name known," etc.

ROUMANIA.

New Commercial Treaty.

With reference to a statement that appeared to the effect that a new commercial treaty between Great Britain and Roumania was signed on the 26th November last, a letter has been received from the Foreign Office stating that the ratifications of this treaty were exchanged at Bucharest on the 31st December last.

Customs Formalities.

The *Journal Officiel* of 22nd December last draws the attention of its readers to the difficulties now thrown in the way of foreign trade in Roumania by the Customs formalities. It is now absolutely necessary that the weight of packages of goods should agree with the statements made in the bill of lading. If there are several articles in one package, the separate weight of each article must be stated, and unless merchants are aware of this regulation much expense and delay may be caused.

TUNIS.

Under the new Customs Tariff of Tunis—which came into operation in August last—the importation of the following articles is prohibited:—Nitrate of soda, saltpetre, gunpowder, dynamite and similar substances, salt, and manures (exclusive of guano, phosphate of lime in powder, etc.).

URAGUAY.

New Customs Tariff.

Articles paying a duty of:—

51 *ad valorem:* Perfumery, powder and ammunition, beer.
47 *ad valorem:* Drugs.
43 *ad valorem:* Candles, matches, and starch.
20 *ad valorem:* Mercury and tar.
12 *ad valorem:* Soda, potash, phosphorus in sticks, and sulphuric, nitric, and chloric (? hydrochloric) acids.
6 *ad valorem:* Scientific instruments; salt.
Free: Sheep dip

CUSTOMS TARIFF OF VENEZUELA.

Rates of Import Duty.

(*Note.*—Bolivar = franc, and is divided into centimes.)

10 *Centimes per Kilo.:* Sulphuric acid.

25 *Centimes per Kilo.:* Stearic and oleic acids and stearine; acetic and hydrochloric acids; nitric acid; colza oil and machine oil; white lead or carbonate of lead; alum; English yellow, or chromate of lead, minium, litharge, and manganese; sulphur in powder and paste; oxide of zinc; ale and cider; chloride of lime; fluid gas; paper of all kinds; paints (common) prepared in oil; potash, common or calcined; saltpetre and salts of nitre; soda, common or calcined; carbonate of soda cryst.; sulphate of iron or copperas; sulphate of copper or bluestone; turpentine, common; vinegar.

75 *Centimes per Kilo.:* Collodion for photographic purposes; varnishes; sperm oil and paraffin; gasoline and benzine; bone dust; baking powder.

1 *Bolivar* 25 *Centimes per Kilo.:* Oils and soaps perfumed; oil of sesame, castor, and other kinds not otherwise mentioned; cod-liver oil; tartaric acid in powder; arsenic and liquid ammonia; quicksilver; colours and paints not otherwise distinguished, such as indigo, ultramarine, etc. drugs, medicines, and chemicals not otherwise mentioned; essences and extracts of every kind not otherwise distinguished; glycerin; phosphorus paste; soap and perfumery; inks, except printing ink; candles.

Importation of the following prohibited: Cocoanut oil, dynamite, starch, white or brown sugar, sarsaparilla, salt.

TRADE BETWEEN SPAIN AND THE UNITED KINGDOM.

Imports from Spain.

PRINCIPAL ARTICLES.		Dec. 1885.	Dec. 1886.
Chemical Products unenumerated	Value	£7,033	£6,584
Copper Ore and Regulus—	Tons	4,291	3,341
	Value	£104,821	£53,270
Manganese Ore	Tons	520	--
	Value	£1,950	—
Pyrites of Iron or Copper—	Tons	55,173	46,671
	Value	£102,886	£90,037
Quicksilver	Lb.	7,420	—
	Value	£500	—
Total Value of Imports		£924,165	£867,183

The total value of imports during January, 1887, amounted to £818,935 as compared with £635,256 in the corresponding month of the year 1886.

Exports from the United Kingdom to Spain.

PRINCIPAL ARTICLES.		Dec. 1885.	Dec. 1886.
Alkali	Cwt.	24,948	24,613
	Value	£8,744	£9,156
Caoutchouc Manufactures	Value	£1,660	£2,057
Cement	Cwt.	8,200	5 000
	Value	£753	£175
Chemical Products, including Dyestuffs	Value	£5,310	£2,058
Products of Coal, including Naphtha, etc.	Value	£2,623	£1,735
Glass Manufactures	Value	£656	£532
Grease, Tallow, and Animal Fat	Cwt.	2,092	1,043
	Value	£2,627	£919
Manure	Value	£8,482	£1,325
Soap	Cwt.	508	251
	Value	£465	£221
Total Value of Exports		£241,868	£253,238

The total value of exports during January, 1887, amounted to £235,826, as compared with £240,097 in January, 1886.

INDUSTRIAL CONDITION OF RUSSIA.

Compared with 1880, the production of manufactured goods in 1884 was as follows:—

	Roubles.	
	1880.	1884.
Cotton	176,203,000	212,226,000
Wool	115,075,000	101,498,000
Linen	27,502,000	30,090,000
Silk	11,476,000	12,647,000
Dyeing	66,640,000	61,252,000
Paper	12,606,000	16,616,000
Chemical Products	15,136,000	22,882,000
Leather	48,819,000	44,791,000
Glass	8 307,000	10,310,000
Porcelain and Faience	2,219,000	3,913,000
Machinery	56,105,000	46,060,000

It will be observed that with the exception of wool, dyeing, leather, and machinery, all these branches of industry show a substantial increase.

ITALY.

Regulations affecting Bills of Lading.

According to the French *Moniteur Officiel*, the Italian Treasury Department has adopted a new system with respect to the presentation of bills of lading by merchants forwarding goods. Formerly, the Customs authorities only required that one bill of lading should be presented, but in future two bills of lading must be delivered to the Customs officers, and consequently the stamp duty is increased from 1 lire 10 to 2 lire 10.

Commercial School at Florence.

Mr. J. G. Kennedy, Her Majesty's Secretary of Embassy at Rome, writing under date of the 21st October last, says:—

"A recent Royal decree has established at Florence a special commercial school, the object of which is to afford special instruction to all intending to become manufacturers, Customs or other Government officials, and for whom a technical knowledge of trade and of commercial geography may be necessary.

"Candidates for the above school must have matriculated in chemistry, graduated at the Lyceum or technical institute, or have completed their studies in a commercial school. Officials of State Departments to whom such instruction may be useful will be admitted to the lectures.

"The course of study will be completed in two years."

GERMANY.

The German Iron and Steel Manufacturers' Union has just published the statistical figures relating to the production during the year 1886.

Pig-Iron Production of the German Furnaces in 1886.

(In tons of 1000 kilos.)

1886.	Puddled and Specular Iron.	Bessemer Pig.	Thomas Pig.	Foundry Pig.	Total Amount of Pig Iron in 1886.	Total Amount of Pig Iron in 1885.

The official statistics furnished by the Government do not as yet come up to the year 1886. During the seven previous years the production was as follows:—

Year.	Puddled Iron.	Bessemer and Specular Iron.	Foundry Pig.	Castings.	Total.
1885	1,885,793	1,300,179	486,816	14,645	3,687,433
1884	1,960,438	1,210,353	414,528	15,293	3,600,612
1883	2,002,195	1,072,357	379,643	15,524	3,469,719
1882	1,901,511	1,153,083	309,346	16,835	3,380,806
1881	1,728,952	886,750	281,613	16,694	2,911,009
1880	1,732,750	731,538	248,302	16,447	2,729,038
1879	1,592,814	461,253	161,696	10,824	2,226,587

During the next few days the Association of Producers of Pig Iron in Rhineland-Westphalia will hold a meeting in order to prolong the present combination, which terminates on June 30.

FOREIGN TRADE OF INDIA.

Chemicals, Drugs, Medicines and Narcotics, and Dyeing and Tanning Materials.

The returns are for the eight months—1st April to 30th November.

DEPRESSION OF TRADE AND INDUSTRY.

Final Report of the Royal Commission appointed to inquire into the Depression of Trade and Industry; with Minutes of Evidence and Appendices.

This is the final report of the Royal Commission on the Depression of Trade and Industry. It contains a *resumé* statement of the information and evidence which are given in previous numbers, of which there have been three issued altogether, Vol. II. being the largest, and consisting of two separate parts.

After tracing the methods adopted by the Commissioners to obtain evidence from Chambers of Commerce, labour associations, foreign countries, and official witnesses on the four subjects or branches of trade selected by them for special inquiry, the report proceeds to give shortly the evidence of some of the principal witnesses on the subject of (1), the iron and coal trades; (2), textile industries; (3), agriculture; (4), shipping. It then deals briefly with the answers given by Chambers of Commerce, labour associations, and Her Majesty's representatives in foreign countries, and further summarises shortly the written and oral evidence given before it. Having thus sketched the evidence, the Commissioners proceed to their conclusions upon it; they review the nature and extent of the depression, and they observe that complaints of depression proceed in a great measure from the producing classes. A general increase of production is everywhere remarkable; statistics of our trade with foreign countries are largely quoted in support of this; also statistics of production, of goods conveyed by railway, and of tonnage entered and cleared are quoted in support of the statement that there has been general increase in production, agriculture alone being in this case an exception. Complaints of absence of profits are many, but against these they have to set the increase of the income-tax, always allowing for greater efficiency of collection. Supply of commodities is, no doubt, they add, in excess of demand, and there has been a reduction in the return to capital.

After giving a summary of the main features of the situation, which are stated to be:—

(*a*.) A very serious falling off in the exchangeable value of the produce of the soil;

(*b*.) An increased production of nearly all other classes of commodities;

(*c*.) A tendency to the supply of commodities to outrun the demand;

(*d*.) A subsequent diminution in the profit obtainable by production; and

(*e*.) A similar diminution in the rate of interest on invested capital.

The report then goes on to review the depression as it effects: (1) the producing classes, (2) the monied class, and (3) the working classes. Having thus dealt with the nature and extent of the depression, the report further remarks on the causes which have assisted to produce the existing state of things. Amongst these the first touched on relates to changes which have occurred in the distribution of wealth, a smaller proportion of profit falling to the share of the employers of labour than formerly, and the employment of labour having become from this cause not so full and continuous. Whether or not the aggregate amount of profit is increasing, the Commissioners think that there is no doubt that profits are becoming more widely distributed among the classes engaged in trade and industry; large capitalists are perhaps receiving a lower return, but the number of those who are making a profit, if but a small one, is much increased. In support of this, figures are quoted from the Reports of Commissioners of Inland Revenue to show that, taking the years 1874–75, 1879–80, and 1884-85, for purposes of comparison, the number of assessments under the head of Trades and Professions, Schedule D, at less than £2000 a-year, has increased at a more rapid rate than the population, whilst the number of similar assessments above £2000 has increased at a less rapid rate, and the number of similar assessments above £5000 has actually diminished, and the Commissioners remark further that the lower the income the more rapid has been the rate of increase. But in addition to this change in the distribution of wealth, there has been over-production—an over-production to which a stimulus was originally given by the great demand for all manufactured goods which followed the war of 1870–71. A demand only temporary was treated as if permanent, and manufacturers increased their power of production as if the demand was to be of a lasting character. Limited liability companies and the operation of the promoters of such companies had much to do with the continuance of this over-production, new companies always springing up, even on the ruins of the old. At the same time bad seasons and the competition of the produce of other countries caused the agricultural section of the community to become seriously crippled, and a lack of purchasing power resulted from the agricultural classes having to accept smaller prices for such produce as they had to offer. Added to this, the stimulus of protection in other countries has made foreign markets less profitable for our trade, in proportion as they became more subject to restrictive tariffs. A diminution of demand for our goods in the home market also took place at the same time as the diminution from abroad.

The diminution of the demand from abroad—not in bulk, but rather in value—has been caused in a great measure by German competition, more especially in the East. Other and minor causes have been at work, such, for instance, as deterioration in the quality of the goods supplied, low-priced goods of an inferior quality having replaced in a great measure those formerly supplied.

Fraudulent marking, practised chiefly by foreign firms, has been another cause at work, and some witnesses are of opinion that restrictions on the employment of labour, together with strikes and similar movements, are making production costly in this country. The Commissioners add, however, that in their opinion the condition of trade and industry cannot with justice, be attributed to the action of trades unions and similar combinations.

The Commissioners further state that they cannot attribute the depression of trade in any way to the incidence of taxation: in fact, we are in this respect in a more favourable position than the foreign countries who compete with us in the markets of the world.

Complaints have been numerous as to the prevailing depression being aggravated by the difficulties connected with the transport of goods. These complaints the Commissioners have divided into three classes:—

(a) That the railway companies regulate their charges so as to favour one district, or place, or trade, at the expense of another, and the importer of foreign goods at the expense of the home producer.

(b) That the cost of transit in this country is excessive, as compared with the charges made for similar services in other countries, and that, consequently, our home trade is being crippled and destroyed to the advantage of our foreign competitors, who are able to place their goods in our markets at a less expense than the home producers, who carry on their operations at a much less distance.

(c) It is contended that if the water communications of the country were properly developed, an effective competition would thus be established, which would obviate any monopoly now possessed.

The Commissioners examined into the arguments adduced to them, their conclusions generally being against those under heads *(a)* and *(b)*, but in favour of that under *(c)*. They then pass on to minor causes which have contributed to the depression, such as the royalties on minerals, which are stated by some witnesses to be excessive; the demand which formerly existed for railway material, and which has now fallen off, the substitution of steel for iron, and consequent economy of material.

Having thus reviewed the prominent features of our commercial position and the forces which have contributed to bring it about, the Commissioners proceed to enumerate certain definite recommendations which they have to make. Amongst these are:—(1) A cheapening of cost of production; (2) increased vigilance in competition with foreign countries; and (3) more particularly a search for new markets. They also consider that technical education is much neglected, and commercial geography might, they think, be studied to advantage.

Suggestions have been made to them that diplomatic and consular agents abroad might render assistance in foreign markets, and the Commissioners weigh the arguments for and against the course proposed.

Full statistics of internal or home trade, they think, might with advantage be collected.

With regard to the questions affecting the charges for railway carriage, the Commissioners remark *(a)* that greater facilities should be afforded to the public for readily ascertaining the rates which the companies profess to charge, together with any modifications of those rates which they make in favour of any individuals or any classes of their customers; *(b)* that a cheap and effective procedure should be provided for obtaining a legal decision on any disputed point, and for enforcing the decision when given; *(c)* that greater attention should be paid to the development of the water communications of the country, and that no railway company should be allowed, either directly or indirectly, to control or own a canal; *(d)* that every facility should be afforded by Parliament for the construction of light railways or tramways in those parts of the country which may be found to be insufficiently supplied with the means of communication, or which are susceptible of further development in this respect.

Legislation, the Commissioners think, might well be instituted with reference to counterfeit marking and fraudulent description of goods. The law relating to limited liability companies they also think capable of improvement, with a view to checking the creation of unsound companies, but they refrain from making specific suggestions, as they are of opinion that the subject requires to be further considered and discussed.

The foregoing report is signed by eighteen out of the twenty-three Royal Commissioners appointed, but of this number only seven sign it without reservations or remarks.

Amongst those who make reservation are Mr. Sclater-Booth, Mr. Cohen, Mr. Gibbs, Mr. Jamieson, and Mr. Palgrave, who consider the report too optimistic, and think that it minimises the depression which has been proved by the evidence to exist; Mr. Birtwistle, who makes some suggestions with regard to fraudulent marking and limited liability trading. Sir James Corry has also some remarks upon the latter subject, and Sir C. M. Palmer thinks that the minority report, signed by Lord Dunraven, Mr. Ecroyd, Mr. Lubbock, and Mr. Muntz, more accurately describes the extent and severity of the depression of trade and industry.

Professor Bonamy Price and Mr. Samuel Storey are also dissentients, but from one paragraph only in each case.

A minority report drawn up by the Fair Trade members of the Commission—namely, Lord Dunraven, Mr. Ecroyd, Mr. Lubbock, and Mr. Muntz, is also appended. It lays stress on some points which are lightly passed over in the majority report, and advocates import duties to countervail, as far as possible, the effect of foreign bounties and protective duties.

A third report is annexed, signed by Mr. Arthur O'Connor, who differs from the rest of his colleagues.

Monthly Patent List.

I.—GENERAL PLANT, APPARATUS, AND MACHINERY.

APPLICATIONS.

719 H. Woodcock and T. Riley, Birmingham. Mode of soldering or brazing earthenware and metallic pipes or other like objects for sanitary, chemical, or other purposes. January 18

751 J. Kendall, Shipley. Protecting flues and generating steam in vertical and other boilers, which he calls "The Kendall flue protector and steam generator." January 18

761 G. D. Hughes and D. Hughes, Nottingham. A furnace bar and smoke consuming furnace. January 18

791 A. H. W. Brown, London. Improvements in means for economising fuel and consuming smoke in steam boiler and other furnaces. January 18

820 W. Oram, Manchester. Improvements in hydraulic presses. January 19

827 St. John Vincent Day, Glasgow—From P. S. Swan, India. An improved door for furnaces to which hot air is supplied for the combustion of the fuel therein. January 19

832 H. J. P. Jolly, London—From G. Richmond, New York. Method and apparatus for artificial cooling. Complete specification. January 19

833 St. John Vincent Day, Glasgow—From P. S. Swan, India. Furnaces for heating air, and apparatus connected therewith. January 19

836 G. G. Campbell, London. Supplying heated air to bottoms of firegrates by means of a hot-air regulator. January 19

991 J. Y. Johnson, London—From H. J. Drory, Austria. Apparatus for spraying and burning liquid fuel for heating steam boilers, or for other purposes. January 21

1089 H. Dansey, London—From L. C. Auldjo, New South Wales. Apparatus for condensing in vacuo for ships' use. January 21

1112 J. Johnson and C. D. Greenland, London. Improvements in decorticating apparatus. January 24

1181 A. Conacher, London. Improvements in refrigerating machines. January 25

1211 J. Barber and J. Fortune, Manchester. Apparatus for preventing the incrustation of the tubes of boilers. Jan. 26

1249 W. L. Cooper, London. Apparatus for the purification and softening of water or other liquids. January 26

1315 W. Bergh, London. Centrifugal apparatus for separating fluids of different specific gravities. January 27

1326 E. Seger, London. An arrangement for driving separators and other centrifugal apparatus. Complete specification. January 27

1336 C. C. Barton, London. Method and apparatus for maintaining a proportional flow of liquids through pipes of the same or of different diameters. January 27

1136 A. W. Beonis, Liverpool. Improvements in or appertaining to apparatus for supplying fuel to furnaces. Jan. 29

1582 A. J. Boult, London—From S. W. Merryman, United States. Improvements in boiler cleaning compounds. Complete specification. February 1

1678 D. Duvilers, London. Improvements in carburettors. February 2

1702 J. Vicars, T. Vicars, and J. Vicars, jun., Liverpool. Improvements in apparatus for feeding fuel to furnaces. February 3

1770 J. Murrie, Glasgow. Improvements in apparatus for indicating or regulating temperature or pressure. February 4

1817 W. G. Hicks, Ramsgate. Improvements in taps for regulating the flow of tar or other like liquids. February 5

1914 E. Green, Nottingham. Improvements in firebars for furnaces. February 8

1915 W. Begg, Manchester. Improvements in the construction of furnaces. Complete specification. February 8

2075 W. Young, London. Improvements in filtering papers. February 10

2085 A. Purvis and W. Purvis, Glasgow. Improvements in hydraulic valves. February 10

2119 F. M. Spence and D. D. Spence, Manchester. Improvements in furnaces for heating, drying, or calcining certain mineral or other substances or materials. February 10

2127 J. Brock and T. Minton, London. Improvements in filter-presses. February 10

2131 P. M. Justice, London—From J. Macdonald, United States. Improvements in apparatus for pumping liquids. February 10

2150 J. Y. Johnson, London—From R. Seguela, France. Improvements in injectors. Complete specification. February 11

2151 P. Keil, Liverpool. See Class X.

2153 C. Johnson, Sunderland. Improved construction of furnaces and closed fires. February 11

2177 H. Holden and R. G. Brooke, London. Improvements in injectors. February 11

2192 H. D. Cooper, London. An improved form of washer especially suitable for the joints of tubes and fittings lined with glass or other material. Complete specification. Feb. 11

2211 F. N. Mackay and A. G. Christiansen, Liverpool. Improvements in means and apparatus for effecting refrigeration. February 12

2219 A. K. Irvine, Glasgow. Improvements in pressure regulators for gas and other fluids. February 12

2228 J. Gilmour, Glasgow. Improvements in and connected with forced blast steam-boiler furnaces. February 12

2231 J. Crosfield and E. Beck, Liverpool. Improvements in apparatus for mixing two or more granular or pulverulent materials in approximately definite proportions. February 12

2237 H. D. Cooper, London. Improved fittings for tubes lined with glass or other material. Complete specification. February 12

2251 J. H. Johnson, London—From A. Leon, France. Improvements in tubes or conduits for gas, water, electric conductors and the like. February 12

2316 H. H. Lake, London—From B. Roberts, United States. Improvements relating to smoke condensing apparatus for use in connection with steam-boiler and other furnaces. Complete specification. February 11

2319 A. Conacher, London. Improvements in refrigerating machines. February 11

2333 S. Kilby and H. Mobbs, Northampton. Boiler explosion preventer. February 15

2341 H. T. B. Sanderson, South Shields. Stopping tubes burst by external pressure. February 15

2398 T. Rawson, Sunderland. The circulation and purification of the water in steam boilers whilst at work, thereby preventing the formation of incrustation or scale. February 16

2433 P. Calliburces, London. Improvements in the system of hygrometers and other analogous instruments and apparatus. Complete specification. February 16

2437 F. Labbé, London. Improvements in furnaces for burning lime, and for other purposes. February 16

2471 J. M. McMurtrie, Glasgow. Improvements in apparatus for regulating fluid pressures. February 17

2485 J. J. Moffat, Birmingham. Improved apparatus for condensing steam. February 17

*COMPLETE SPECIFICATIONS ACCEPTED.**

1886.

1938 T. Derham. Certain improvements in hydrometers and saccharometers. February 9

2651 A. Myall—From J. McIntyre. Surface condensers. February 19

3270 C. S. Madan. Injectors for raising and forcing fluids, and feeding boilers. January 22

3731 C. W. Burton and F. T. Moison. Apparatus and method for purification of water. January 29

3801 J. Anderson and R. McKinnell. Apparatus for inducing or producing currents of air, water, or other fluid

3878 R. Hanson and J. Fernee. Improvements in open-hearth furnaces, applicable to other heating purposes. Feb. 2

3897 W. Sellar. Apparatus for heating, purifying and filtering water for feeding steam boilers, pumps, suction pipes, etc. January 26

4135 F. Mörth. Apparatus for supplying liquid or gaseous fuel to furnaces, etc. January 26

4244 A. C. Kirk, Glasgow. Improvements in feeding, and in feed-heating apparatus. January 26

4497 T. W. Beverley. Blowing apparatus. February 2

4518 M. Reuland. Apparatus for drying semi-fluid and other substances. February 2

4601 B. D. Healey. Gas-fired furnaces. February 5

4623 P. Hikely and J. Radcliffe. An improved filter. Feb. 19

4681 J. G. Kinghorn. Valves for air circulating, air compressing, and other pumps. February 2

4684 J. Ross. Valves and fittings for steam, water or other fluids. February 2

4700 E. N. Henwood. Construction and arrangement of furnaces for burning hydrocarbon oils in conjunction with compressed air or steam. February 5

4871 G. F. Redfern—From M. H. Simonet. An improved grinding and triturating machine. February 9

4878 W. F. B. Massey Wainwaring. Improvements in filter-presses, and in drying sewage sludge and other moist matters. February 9

5014 W. G. Wrench. Apparatus for removing scale from steam boilers. February 12

5114 J. Wright. Construction of steam and water taps. February 16

5251 C. E. Davis. Apparatus for mixing liquids. Feb. 16

5252 E. B. Donkin. Four-way bye-pass valves for gas and other fluids. February 16

5305 T. Gilmour. Feed-heating apparatus. February 16

5343 C. E Gittens. Filters. February 16

5515 A. Waldbaur. Centrifugal machines. January 26

7022 J. C. Mewburn—From J. Dietze, Germany. Surface cooling, heating, and condensing apparatus. January 26

9759 E. Jones and A. Beech. Filter-presses and mode of charging same. February 9

10880 T. D. Williams. Amalgamating apparatus. January 26

12371 H. Lane and R. H. Taunton. Manufacture of metallic vessels for containing gases and volatile liquids under pressure. February 16

13336 A. J. Boult—From W. A. O. Hegeman. Fluid pressure regulators. February 19

15787 H. Wilson. Apparatus for creating forced draught and forced combustion, and for injecting fuel into furnaces, and the like. January 29

16135 E. Kaslowsky. Apparatus for pumping and compressing air. January 22

16991 H. E. Newton—From W. M. Deutsch. Filtering apparatus. January 29

1887.

334 J. Simpson. Lids or closers for metallic drums or casks. February 12

II.—FUEL, GAS, AND LIGHT.

APPLICATIONS.

816 W. Pursall, Birmingham. A new or improved means of illumination. January 19

927 S. Levy, London—From G. H. Kohn, United States. Improvements connected with the manufacture of water gas and other gases for lighting, heating, and manufacturing purposes, and in apparatus therefor. January 20

1132 F. Windham, London. Improvement in the manufacture of gas for use in gas engines. January 25

1134 J. A. Yeadon and R. Middleton, Leeds. Improvements in blocks or briquettes of fuel or materials for smelting, or analogous purposes. January 25

1139 J. J. Royle, London. Improvements in and apparatus for preparing coke for use in slow-combustion stoves. Jan. 25

1150 J. S. Sellon, London. Improvements in apparatus for lighting by the consumption of gas and air. January 25

1171 G. H. Fenner, London. Improvements in the manufacture of naphthaline into forms suitable for use in illumination, and in apparatus employed therein. January 25

1297 F. A. McMino, London. The manufacture of inflammable gas from oil. January 27

1376 E. Davies, London. Improvements in lighting and heating, and in apparatus therefor. January 28

1478 S. Wilkinson and J. Clarkson, London. Improved means of and apparatus for heating and diffusing air for warming and ventilating purposes. January 31

1479 A. G. Meeze, Redhill. Improvements in apparatus for the manufacture of gas from fluid hydrocarbons. January 31

1490 J. Atterton, Haverhill. Improvements in apparatus for charging gas retorts. January 31

1511 P. Ward and W. S. Oliver, London. Improvements in light-producing apparatus. January 31

1515 H. Schlichter, London. A method of lighting by means of gas, and apparatus therefor, which method and apparatus may be made to serve also for deodorising and disinfecting the atmosphere. January 31

1538 E. Sherring, Manchester. The application of asbestos to oil lamps and oil stoves and burners as a non-conductor of heat. February 1

1551 J. Torkington, J. A. Ewins, and C. Torkington, Birmingham. Improved means of economising gas for lighting and heating purposes. February 1

1684 W. H. Lindsay, London. Improvements in the manufacture of artificial fuel. February 2

1767 J. H. R. Dinsmore, Liverpool. Improvements in the manufacture of gas and apparatus therefor. February 4

1965 J. Birchall, London. Improvements in the manufacture of gas and apparatus therefor. February 8

2092 L. A. Brode, Glasgow. An improved method of utilising the waste and dross of coal in the manufacture of briquettes for use as fuel. February 10

2099 J. A. Drake, Halifax. Improvements in the method of and apparatus for generating heat in steam boilers, baking ovens, blast furnaces, gas retorts, and the like. February 10

2186 M. P. W. Boulton, Tew Park, Oxfordshire. A method and apparatus for the combustion of fuel. February 11

2210 S. F. Rhodes, London. Improvements in apparatus for converting into spray or vapour, hydrocarbon oils or other liquids, and for burning, gasefying, and evaporating the same. February 12

2313 C. D. Abel, London—From the Gas Motoren-Fabrik, Germany. Improvements in apparatus for vapourising liquids giving combustible vapours. February 14

COMPLETE SPECIFICATIONS ACCEPTED.

1886.

2156 J. E. Mathewson, Sheffield. The separation of steam or other vapours or gases from liquids mixed with them. February 17

2766 W. L. Wise—From F. J. Lothammer. Portable apparatus for the manufacture of gas. January 29

3663 S. Pitt—From C. Haret. Preservation of inflammable matters, and composition for rendering bodies uninflammable, and for extinguishing fire. February 19

3697 F. Windham. Manufacture of gas for use in gas engines. January 22

4220 M. P. W. Boulton. Improved application of heat to generating and heating steam. January 22

4451 G. King. Fastenings for retort lids. February 5

4582 W. A. Barlow—From J. F. W. A. Jahnke. Lamps and lanterns for burning carburetted coal-gas. February 5

4617 J. Dillamore. Apparatus for removing tar from the hydraulic mains used in the manufacture of coal-gas. Feb. 5

5348 W. W. Box. Gas retort lids and fastenings. Feb. 16

10891 W. Finlayson—From R. H. Martin. Preparing asbestos for use as a non-conductor of heat and otherwise. February 12

16112 F. B. Fowler. Mode, means, and appliances for making oil-gas. January 22

16992 R. S. Lawrence. Carburettors and gas generators, January 29

---

* The dates given are the dates of the Official Journals in which acceptances of the Complete Specifications are advertised. Complete specifications thus advertised as accepted are open to inspection at the Patent Office immediately, and to opposition within two months of the said dates.

1887.

740 A. Kitson. Gas apparatus, and process for generating illuminating gas. February 19

III.—DESTRUCTIVE DISTILLATION, TAR PRODUCTS, Etc.

COMPLETE SPECIFICATION ACCEPTED.

1886.

3738 G. T. Beilby and J. B. McArthur, Slateford. Utilising hydrocarbon gases obtained in the distillation of petroleums, rosin, etc. January 29

IV.—COLOURING MATTERS AND DYES.

APPLICATIONS.

875 G. Thomas, Manchester—From A. Zander, Prussia. The manufacture of dye matters from red sanderswood and certain other woods. January 20

968 A. G. Green, London. The manufacture of new azo and nitro colouring matters. January 21

1657 C. J. Smith and J. S. Tanner, London. Improvements in marking ink. February 2

1694 O. Imray, London—From the Farbwerke vormals Meister, Lucius and Brüning, Germany. Improvements in the production of alkylised diamidobenzophenon amine chlorides and conversion of the same into alkylised diamidobenzophenones and yellow colouring matters of the class of the "auramines." February 3

COMPLETE SPECIFICATION ACCEPTED.

1886.

4687 T. Maxwell and J. Young. Manufacture of colouring matter. February 5

V.—TEXTILES, COTTON, WOOL, SILK, Etc.

APPLICATIONS.

1026 H. Ainley and G. W. Tomlinson, London. Improvements in means or apparatus for fulling, milling, scouring, and felting woollen and other fabrics or materials. January 22

1263 W. Cook, London. Improvements in and applicable to machinery for washing or scouring wool and other fabrics. January 26

1648 T. Speight, Bradford. Improvements in the method of and apparatus for removing the "bur" in wool and other fibres. February 2

2039 J. W. Smith, Bradford. Improvements in the method of and apparatus for preparing wool and other fibres for spinning. February 9

2089 T. F. Wiley, Bradford. A new or improved process for waterproofing textile fabrics and other porous materials. February 10

2257 F. H. Ford, A. N. Ford, and J. A. Archer, London. The manufacture of a new kind of textile fabric. February 12

2423 G. I. J. Wells and S. L. Howard, Liverpool. Improvements in treating Rhea bark, China grass, or other material of similar nature, and in apparatus applicable therefor. Feb. 16

COMPLETE SPECIFICATIONS ACCEPTED.

1886.

2226 J. P. Land and C. P. King. Apparatus for carbonising and destroying vegetable matter in wool. February 16

16116 H. H. Lake—From H. R. Randall. Treatment of silk and other fibres. January 26

VI.—DYEING, CALICO PRINTING, PAPER STAINING, AND BLEACHING.

APPLICATIONS.

818 J. Walker, Halifax. Improvements in the method of and apparatus for dyeing or otherwise treating textile fibres. January 19

1222 A. Smith, Bradford. Improvements in apparatus for dyeing. January 26

1351 W. Birch, Manchester. An improvement applicable to machines for washing, soaping, dyeing, and dunging woven fabrics. January 28

1610 J. S. Sutcliffe and J. S. Smith, Manchester. Improvements in or applicable to sizing machinery. February 2

1816 A. J. Boult, London—From F. Rubay, Belgium. Improvements in the bleaching of vegetable tissues. February 4

1831 W. Birch, Manchester. Improvements in rollers used in washing, soaping, dyeing, and other similar machines. February 5

1990 E. Hermité, J. Paterson, and C. F. Cooper. See Class XVIII.

2123 H. H. Lake, London—From L. Whitefield, United States. An improved compound for producing designs upon textile fabrics and for similar purposes. Complete specification. February 10

2351 A. J. Boult, London—From H. K. de Pawlowski, France. Improvements in the process and apparatus for bleaching of vegetable and animal matter. February 15

COMPLETE SPECIFICATIONS ACCEPTED.

1886.

6988 J. Smith. Dyeing cotton, silk, wool, etc., either in the raw or manufactured state, and apparatus therefor. Jan. 26

8219 T. Hauschel. Apparatus for washing, dyeing, drying, etc., wool, cotton, and other textiles or fibres. February 19

16596 C. Corron. Machine for dyeing hanks or skeins of textile materials. January 26

VII.—ACIDS, ALKALIS, AND SALTS.

APPLICATIONS.

765 C. A. Burghardt and A. H. Tuer, Manchester. An improved process or processes for the purification of bisulphide of carbon. January 18

872 P. Hart, Manchester. Improvements in and relating to apparatus employed in the concentration of sulphuric acid. January 20

1749 R. Hamilton, Glasgow. Improvements in the recovery of ammonia and carbonic acid from liquors containing these, and in appliances therefor. February 3

1832 J. Mangnall, Manchester. Generating carbonic acid gas, and apparatus connected therewith. February 5

1856 T. Schmidt, London. A process for the manufacture of certain salts of sodium and potassium, producing also gypsum and hydrochloric acid. February 5

1973 W. B. Cogswell, Liverpool. An improvement in bicarbonate columns. February 8

1974 L. Mond and D. B. Hewitt, Liverpool. Improvements in the manufacture of caustic soda or caustic potash, and of carbonic acid from mono or other carbonate of soda or potash. February 8

1998 A. M. Clark, London—From J. Brown, F. Herreshoff, W. H. Nichols and G. H. Nichols, United States. Process of making pure sulphuric and strong sulphuric acid in one continuous operation. Complete specification. February 8

2402 C. Wigg, Liverpool. An improved process for obtaining bicarbonate of soda. February 16

2403 C. Wigg. The treatment of spent copper liquors and the application of the product for the purification of sewage and like matters. February 16

COMPLETE SPECIFICATIONS ACCEPTED.

1886.

1832 A. M. Clark—From O. Eyckens. Producing lead salts, and especially carbonate or oxycarbonate of lead (white lead). February 9

3238 L. Mond. Obtaining ammonia, chlorine and hydrochloric acid from ammonium chloride. February 9

3956 J. H. Johnson—From E. Hermité. Producing ozone and hydrogen for bleaching purposes. January 22

3957 J. H. Johnson—From E. Hermité. Producing chlorine compounds suitable for bleaching purposes. January 22

4070 E. Arthur and E. M. Arthur. Process for obtaining crystallised sulphate of calcium. February 2

4737 G. J. C. Marie. Caustic powders for the removal of paint and other deposits. February 5

4742 H. L. Pattinson, jun. Treating tersulphides or polysulphides of barium and strontium so as to recover the barium and strontium, and obtain other products. February 9

5016 J. H. Johnson—From J. L. Kessler. Process for expelling sulphuric acid in excess from sulphates and bisulphates. February 12

7199 J. Brock and T. Minton. Manufacture of bleaching powder, and apparatus therefor. February 9

15436 H. Byk. See Class XX.

VIII.—GLASS, POTTERY, AND EARTHENWARE.

APPLICATIONS.

830 J. P. Guy, Burslem. A saggar placing and drawing machine for potters' ovens. January 19

967 W. Cliff, London. Improvements in the manufacture of fire-clay enamelled baths. January 21

1015 R. E. Donovan, F. Hazlett and J. Johnson, Dublin. Improved apparatus for blowing glass by means of compressed air. Complete specification. January 22.

1151 C. M. Pielsticker, London. Improvements in the manufacture of plate glass. January 25

1339 H. R. Yeo, Plymouth. Producing transparencies on coloured or ground glass for ornamental or other purposes. January 28

1131 D. Rylands and B. Stoner, Barnsley. Improvements in means for blowing bottles or other hollow glass-ware. January 29

1411 P. Graham, Glasgow. Improvements in and connected with the manufacture of hollow clay-ware, and in potters' jollies, or machines therefor. January 29

1565 M. Wyatt, London. An impermeable earthenware coffin. February 1

1733 W. Reynolds, London. An improved substitute for stained glass. February 3

1911 J. Critchlow, T. Forester, W. Forester, H. Forester and L. Forester, Longport. An improved potters' filter-press. February 8

2111 O. C. Hawkes, London. New and improved machinery for bevelling and moulding the edges of plates of glass and for ornamenting the surfaces of plates of glass. February 10

2253 T. Wickham and J. Nall, London. Improvements in tools for forming the exterior of bottle necks. February 12

2256 T. Wickham and J. Nall. Improvements in tools for forming the interior of bottle mouths. February 12

2271 A. Fielding, Longport. An improved differential speed and reversing motion for potters' lathes. February 14

2292 W. P. Wilson, London. Improvements in apparatus or tools for shaping the necks of bottles and other like receptacles. Complete specification. February 14

2305 H. L. Doulton and W. Parker, London. Improvements in ornamenting pottery, tiles or glass. February 14

2330 J. T. Creasy, London. An improved tool for glazing the edges of the necks of glass bottles and jars of any configuration. February 15

2380 W. B. Fitch, London. Improvements in the manufacture of glass bottles, and apparatus therefor. February 15

COMPLETE SPECIFICATIONS ACCEPTED.

1886.

3369 J. D. Denny. Embossed and geometrical tiles and mosaics, and appliances for making the same. February 19

3391 S. J. Payne. Manufacture of fire-bricks, retorts, crucibles, etc. February 2

3615 O. Lindner. Decoration of earthenware and other surfaces. January 29

4282 T. Ide. Moulds for bending plate and sheet glass. January 26

4325 H. Norris. Colouring glass, porcelain, china and other substances to imitate stained glass. January 29

5187 W. Walker. Ornamenting glass, and applying it to architectural purposes. February 16

16877 W. Boulton. Apparatus for making bats for use in the manufacture of various articles of pottery. January 26

1887.

1015 R. E. Donovan, F. Hazlett and J. Johnston. Apparatus for blowing glass by means of compressed air. February 16

IX.—BUILDING MATERIALS, CLAYS, MORTARS, AND CEMENTS.

APPLICATIONS.

781 H. McDonnell, J. J. Mallon, and G. W. Clark, London. Process of forming ornamental coverings for walls, ceilings, and other surfaces. Complete specification. January 18

979 W. E. Gedge, London—From J. Thorrand, V. Nicolet, and A. Bonnet, France. A novel artificial cement. Complete specification. January 21

1039 C. Schlickeysen, London. Improvements in apparatus for moulding bricks, tiles, and similar articles. January 22

1759 C. J. Ford, London. Improvements in surface tiles for walls, partitions, ceilings, floors, etc. February 4

1919 P. Cornish, Stratford. Improvements in road pavements and curb stones. February 7

2008 G. Evans, London. Improvements in roof tiles, single lap and weather-tight. February 9

2302 T. Smith, London. An improved method of utilising metallic and other cements, plaster of Paris, and such like substances. February 14

2363 D. N. Arnold and W. Young, London. Improvements in cements. February 15

2182 W. Tuffee, London. Improvements in the manufacture of Portland cement and apparatus therefor, applicable also for making bricks, tiles, and other similar articles, and for burning lime and other materials. February 17

COMPLETE SPECIFICATIONS ACCEPTED.

1886.

1816 W. Joy. Method of charging cement kilns. February 9

2566 P. Bowden. Machinery for the manufacture of bricks and tiles. February 19

3121 W. Macleod. Laying pavements of wood, tiles, concrete, etc. February 5

3449 C. E. Davis. Improvements in tiles for roofing. Feb. 2

3569 J. Dyson, Wakefield. Construction of wall-bonds or bricks for preventing damp walls. January 22

3715 P. Freygang. Rotary drying and crushing apparatus for clay, etc. January 22

4245 J. Brierley. Floors of wood and earthenware combined. February 2

4332 G. H. Couch. Ridge, hip, and wall tiles. February 2

4547 W. Johnson. Machinery for manufacture of bricks from plastic and semi-plastic materials. February 2

4872 D. Coltier. Production of imitations of stone, marble, terra-cotta, etc., for decorative purposes. February 5

1887 S. G. L. Giles and W. J. Petrie. Method of decorating Lincrusta Walton, and other embossed materials for the decoration of walls. February 12

6126 W. Parry. Improved construction of floors, roofs, and arches of brick, terra-cotta, stone, etc. January 22

9536 E. T. L. Clark. Hardening and preserving plaster of Paris casts and moulds, and rendering the same impervious to water. February 16

15211 J. V. Johnson—From E. Coignet. Preparation and treatment of beton or concrete, and apparatus therefor. February 12

17098 W. Sonnet. Mode and apparatus for continuously manufacturing Portland cement. February 9

1887.

578 P. M. Justice—From C. Dietzsch. Furnaces or kilns for calcining limestone, etc. February 16

781 H. McDonnell, J. J. Mallon, and G. W. Clark. Process for forming ornamental coverings for walls, ceilings, etc. February 19

X.—METALLURGY, MINING, Etc.

APPLICATIONS.

803 P. M. Justice, London—From W. V. Shelton, Turkey, Improvements in the production of alloys or bronzes. Jan. 18

815 J. H. Selwyn, London. Method or process of treating pyritiferous or other base ores to extract metals therefrom. January 19

921 C. D. Abel, London—From E. Fischer and M. W. Weber, Germany. Improvements in extracting gold and other precious metals from their ores, and apparatus therefor. Complete specification. January 20

943 A. E. Tucker and F. W. Harbord, Smethwick. Improvements in the manufacture of iron and steel. January 21

993 W. Jenisch and H. Lohnert, London. Improvements in mills for crushing, pulverising, grinding, or reducing. Jan. 21

1069 W. H. Edwards, C. Britton, and J. E. Williams, Birmingham. Improvements in miners' safety lamps. January 24

1078 A. Harper, London. A novel description of compound castings of iron and steel specially suitable for chill and grain rolls, and means for producing the same. January 24

1166 S. B. Stine, London. Improvements in coal mining machines. Complete specification. January 25

1211 R. Thompson, Liverpool. Improvements in getting, winning, or mining coal, and in drilling and other apparatus therefor. January 26

1258 W. S. Squire and S. C. G. Currie, London. Obtaining metallic zinc. January 26

1261 D. McCorkindale and G. Dougall, Glasgow. Improvements in and connected with stoppers used in the manufacture of steel. January 26

1270 H. H. Lake, London—From G. and A. Raymond, United States. Improvements relating to the pulverisation or reduction of mineral or other substances, and to apparatus therefor. January 27

1276 E. Cleaver, London. Improvements in the manufacture of aluminium and aluminium alloys. January 27

1279 W. Patterson, Durham. Improvements in miners' safety lamps. January 27

1290 F. W. Paul, Glasgow. Improvements in making iron or steel. January 27

1305 E. H. Cowles, London. Improvements in alloys of aluminium and chromium with iron or steel. January 27

1322 W. H. Tooth, London. Improvements in the manufacture and refining of iron, and the conversion of iron into steel, and apparatus connected therewith. January 27

1388 W. G. Olpherts, London. A novel application and mode in connection therewith of utilising old or waste railway rails. January 28

1121 C. Roy, London. Improvements in rolling mills. January 29

1181 J. Hayes, Broughton Moor. A mining level. January 31

1189 H. O. A. E. Grunbaum, London. Improvements in the means or a light improving safety lamp for magnifying the illuminants and preventing accidents. January 31

1535 C. M. Pielsticker, London. Improvements in apparatus for the continuous production of metal bars and rods direct from the molten metal. February 1

1700 J. G. Wright, Wolverhampton. Eliminating from pig or cast iron the impurities or metalloids, silicon, sulphur, and phosphorus. February 3

1750 and 1751 H. H. Lake—From Count R. de Montgelas See Class XVIII.

1918 A. H. Read, London—From H. G. Hicks, United States. Certain improvements in welding compounds. Complete. specification. February 7

1921 C. Dickenson, London. Improvements in chills for casting iron, steel, and other metals. February 7

2056 J. Douglas, London. An improved miners' safety lamp. February 9

2060 W. Gentles, London. Improvements in the manufacture of copper, February 9

2149 A. Feldman, London. Improvements in the production of fluoride of magnesium and fluoride of aluminium. Feb. 11

2151 P. Keil, Liverpool, New and improved furnace applicable for the reduction of zinc and other ores containing volatile metals, and for other dry distillation processes. February 11

2168 T. Freeman and D. R. Jenkins, London. Improvements in means or apparatus to be employed in, or connected with, the coating of plates with tin or terne, or other metals. Feb. 11

2190 F. N. Wardell and J. Mitchell, London. Improved apparatus for preventing the accidental descent of cages in the shafts of mines. February 11

2216 C. Poole, Blyth. Drilling coal. February 12

2220 E. V. Seebohm, London. Improvements in the manufacture of silicon steel. February 12

2230 W. W. Curley and J. Hall, Sheffield. Improvements in hardening steel or compound iron and steel for use in the manufacture of tools and other steel or iron and steel articles, and in furnaces or apparatus therefor. February 12

2245 F. M. Spence and D. D. Spence, Manchester. Improvements in certain furnaces for heating, drying, or calcining certain mineral or other substances or materials. February 12

2306 T. Slater, London. Improvements in metallic alloys. February 14

2312 R. Stanley, London. An improved boring or tunnelling machine. February 14

2390 H. Leipmann, London. See Class XVIII.

2447 C. Sheibler, London. Improvements in the manufacture of steel and iron, and in obtaining by-products of such manufacture. Complete specification. February 16

2488 W. Macfarlane, Leeds. An improvement in the production of steel. February 17

2499 C. Fairbairn and M. Wells, London. An apparatus for forging by rollers conoidal projectiles and other articles of circular transverse section. February 17

COMPLETE SPECIFICATIONS ACCEPTED.

1886.

1102 W. Tooth. Method and means for extracting spelter, and apparatus for treating the waste products. January 26

1288 G. Perry—From M. Perry. Obtaining compounds of cobalt from solutions of the same. January 29

1289 G. Perry—From M. Perry. Obtaining compounds of cobalt from solutions containing the same. January 29

1173 H. H. Lake—From La Société de Laminage du Nickel. Uniting platinum or silver and nickel or alloys of these metals. February 5

2785 W. J. Smith. Safety electric lamp for miners. Jan. 22

3632 L. A. Groth—From C. Beckstein. Powder for hardening metals. January 29

3746 J. F. Hall, Sheffield. Armour plates. January 22.

3821 J. E. Williams. Safety lamps for use in mines. Jan. 26

3971 J. M. Macdonald—From T. D. Williams. Stamps for crushing quartz and other ores. February 5

3986 J. M. White. Furnaces for the manufacture of metallic sleepers. February 2

4113 G. Dyson, Leeds. Apparatus for securing the chaplets used in supporting cores for castings. January 26

4312 A. Howat. Miners' safety lamps. January 26

4379 C. T. Cayley. Hardening or tempering steel bullets and projectiles, and apparatus therefor. February 2

4602 J. S. Donald. Miners' safety lamps. February 12

5527 A. de Laude Long and R. Howson. A new manufacture of fibrous iron. February 9

6992 L. L. Sagendorph. Machines for corrugating sheet metal. January 29

15103 A. J. Boult—From La Société Anonyme de Métallisation Artistique des Animaux, Végétaux, ou Autres Corps, France. Preparation of organic matter for metallisation by galvanic deposit. January 26

16386 H. E. Newton—From J. J. Crooke and R. Crooke, United States. Process for treating and desilverising copper matte, and copper ores analogous thereto. January 22

XI.—FATS, OILS, AND SOAP MANUFACTURE.

APPLICATIONS.

1033 S. S. Sugden, Woodford. Improvements in the treatment of fatty and oily matters for the production of glycerine, white lead, and soap. January 22

1057 R. Hunt and E. S. Wilson, Liverpool. Improvements in the treatment of cotton seed to obtain oil feeding cake and resin-like matter. January 21

1291 N. M. Henderson, Glasgow. Improvements in apparatus for treating or purifying paraffin wax. January 27

1461 H. M. Roberts and A. W. Doery, London. Improvements in separating fat from liquids and apparatus therefor. January 29

1589 P. Gill and T. Osman, Liverpool. Improvements in apparatus for scraping and cutting soap. February 1

1753 L. Hunter, London. An improved soap tablet. Feb. 3

1771 R. Hunt and E. S. Wilson, Liverpool. Improvements in refining and clarifying crude cotton-seed oil. February 1

1840 W. H. Stead, Liverpool. Improvements in refining cotton-seed oil. February 5

1893 W. Hicks, Middlesbrough. Improvements in the manufacture of lubricating grease. February 7

COMPLETE SPECIFICATIONS ACCEPTED.

1886.

3166 A. Blackie. Preparation of emulsions of vegetable, animal, or mineral oils, of solid paraffins, waxes, etc., and of liquids and fatty substances insoluble or slightly soluble in water. January 22

3518 B. J. Hicks and J. Kirkwood. Lubricating composition. January 22

3719 A. F. Craig, A. Neilson, and J. Snodgrass, Glasgow. Apparatus for separating mineral and other oils from oils or substances of different specific gravities. January 22

4101 J. L. Wade. Lubricating compound. January 26

XII.—PAINTS, VARNISHES, AND RESINS.

APPLICATIONS.

955 H. H. Gunn, Glasgow. Improvements in the manufacture of sulphide of zinc white. January 21

1668 P. Ward and S. W. Oliver, London. Improvements in the pigments for, and in the method of, colouring photographs. February 2

2201 R. E. Donovan and J. McKenny, Dublin. The utilisation of a natural product in the manufacture of blacking, Japan black paint, and varnish, and other similar coloured materials. February 12

2157 O. Jeyes, Birmingham. Jeyes' anti-corrosive compound. February 17

2198 W. Dick, London. A novel protective varnish. Complete specification. February 17

COMPLETE SPECIFICATIONS ACCEPTED.

1886.

1832 A. M. Clark—From O. Eyckens. See Class VII.

17026 J. H. G. Langenhagen. Leather polish. February 9

XIII.—TANNING, LEATHER, GLUE, AND SIZE.

APPLICATIONS.

1009 A. Smetham, Liverpool. Improvements in the manufacture of water-proof leather. January 22

1163 J. H. G. Langenhagen, Liverpool. A new or improved dressing for leather. Complete specification. January 25

1371 A. Tissot, London. Improvements in tanning leather. January 28

1382 E. Page and G. Brayfield, London. The manufacture of a composition for varnishing and reviving leather. January 28

1562 E. Dunkley and A. Dunkley, Northampton. An improved method of making leather water-proof or flexible. February 1

XIV.—AGRICULTURE, MANURES, ETC.

APPLICATIONS.

780 C. E. Hearson and B. Field, London. Improvements in the vaporisation of volatile liquids for the destruction of insects, and in apparatus for the vaporisation of volatile liquids for tho said purpose, and for other purposes. January 18

1130 W. Thompson, Stratford-on-Avon. An improved fertiliser. January 25

2097 H. K. Spark and J. Warburton, Sheffield. See Class XVII.—B.

2457 A. Campbell, Upton Park. The economical mixing or compounding of phosphatic compounds for artificial manures. February 17

COMPLETE SPECIFICATIONS ACCEPTED.

1886.

3167 A. Clemm. Method and means for the destruction of insects and animals injurious to plants and fruits. February 5

5031 N. B. Powter. Treating phosphatic earths and rocks for the manufacture of fertilisers therefrom. February 12

XV.—SUGAR, GUMS, STARCHES, ETC.

APPLICATIONS.

779 H. L. Sulman and E. E. Berry, London. Improvements in apparatus for the manufacture of starch. January 18

986 V. C. A. M. Bondonneau and A. J. M. G. Foret, London. Process and apparatus for acid saccharification of starchy materials. January 21

1931 M. A. Perret, London. Improvements in apparatus for extracting the saccharine or other matter from sugar-cane and other substances. Complete specification. February 7

2297 A. Brin and L. Q. Brin, London. Improvements in the treatment of saccharine and sacchariferous matters for the purpose of decolourising, purifying, or refining them. February 11

2298 A. Brin and L. Q. Brin. Improvements in the treatment of saccharine and sacchariferous matters for the purpose of decolourising, purifying, or refining them. February 11

COMPLETE SPECIFICATIONS ACCEPTED.

1886.

3628 H. E. J. Solwig and K. A. C. B. Lange. Manufacture of sugar blocks and apparatus therefor. January 29

1679 C. W. N. Wallace and C. J. H. Barry. Manufacture of caramel. February 5

1801 C. D. Abel—From P. S. Sohne. Process for the desaccharification of molasses and sugar syrups, and the simultaneous production of oxalates from the salts contained therein. January 22

1918 O. Imray—From A. K. Kissel, Germany. Manufacture of an elastic compound in imitation of caoutchouc. Jan. 26

15400 J. Horning, C. Rabe, and F. J. Weiss. Evaporating apparatus for use in the manufacture of sugar, etc. Feb. 9

1887.

785 W. P. Thompson—From T. Kane. Manufacture of candy. February 19

XVI.—BREWING, WINES AND SPIRITS.

APPLICATIONS.

812 J. Klein, London. Improvements in apparatus for filtering beer and other liquids. January 19

1131 J. Foulis, Musselburgh. Improvements in non-alcoholic medicated liquors or cordials for use as a beverage. Jan. 25

1516 W. Adlam and F. Faulkner, London. Improvements in treating brewers' wort, and apparatus therefor. Jan. 31

1673 J. M. Anderson, Glasgow. Improvements in malting, and in drying malt and grain, and in apparatus therefor. February 2

1880 R. Wood, Cardiff. A process for preparing, moistening, assimilating, and malting barley, grain, and other farinaceous matter by steam. February 7

1992 G. Epstein, London. Improvements in the treatment of brewers' and distillers' grain. February 8

2005 C. Clinch, London. Improvements in brewing. Feb. 8

2057 W. Ansell, London. Manufacture of a non-intoxicating beverage. February 9

2109 H. Grote, London. Process for removing fusel oil from crude spirits, or from the mash containing crude spirits. February 10

2221 J. W. Bailey, Greenock. Manufacturing of a new brewing saccharine. February 12

COMPLETE SPECIFICATIONS ACCEPTED.

1886.

4071 F. Faulkner and W. Adland. Aërating brewers' wort and other liquids, and apparatus therefor. January 26

4191 W. A. How. Apparatus for holding bicarbonate of soda for generating carbonic acid gas for use in aerating ale, etc. February 16

4311 W. W. Crawford. Maturing alcoholic liquors. Jan. 26

4529 E. L. Pontifex. Skimmer for removing yeast from wort in a fermenting vessel. February 2

1868 W. Bradford. Cowls for malt and other kilns, and brewery and distillery utensils. February 5

1887.

328 B. J. B. Mills—From C. Brada. Malt kilns. February 9

XVII.—CHEMISTRY OF FOODS, SANITARY CHEMISTRY, DISINFECTANTS, Etc.

APPLICATIONS.

A.—Chemistry of Foods.

901 H. Gross and P. Hesemann, London. Process and apparatus for roasting coffee. January 20

1106 J. G. Tongue, London—From B. Drenckmann and W. Hildebrand, Germany. Improvements in the means employed to produce fermentation in dough for bread-making. Jan. 24

1772 J. France, Halifax. A new treatment of milk to prevent its turning sour. February 1

1996 J. Cornrick, London. Improvements in the process of and apparatus for manufacturing powdered milk. Complete specification. February 8

2413 W. Smith, London. Improvements in apparatus for separating cream from milk. February 16

2519 H. W. Hart, London. An improved method of treating coffee to prevent loss of its valuable constituents and to preserve the aroma. February 17

B.—Sanitary Chemistry.

799 E. B. S. Benest, London. Disinfecting apparatus. January 18

1333 W. Webslor, jun., London. Improved means of oxidising and decomposing by electrical action organic matter and inorganic salts in sewage, water, and other liquids. January 27

1515 H. Schlichter. See Class II.

1519 H. H. Lake, London—From L. L. Benson and W. T. Stilwell, United States. Improvements relating to means for expelling and rendering innocuous the gases or vapours from sewers and the like. Complete specification. January 31

1525 H. W. Newton, Newcastle-on-Tyne. Eliminating pernicious particles from atmospheric air inhaled. February 1

1699 D. Craig, Bradford. A new or improved means of utilising sewage sludge. February 3

2097 H. K. Spark and J. Warburton, Sheffield. A new or improved method and material to be used for universal sanitary and disinfecting purposes, the said material being afterwards applicable as manure and otherwise. February 10

2388 A. Angell, London. Improvements in the manufacture of precipitants and in the treatment of sewage. February 15

2403 C. Wigg, Liverpool. See Class VII.

C.—Disinfectants.

2235 P. Gros-fils, London. A novel composition for preserving organic substances and method of using the same. Feb. 12

COMPLETE SPECIFICATIONS ACCEPTED.

A.—Chemistry of Foods.

1886.

2461 W. A. Gibbs. Apparatus for withering and drying tea, coffee, wheat, and other granular materials. February 19

2646 A. M. Clark—From A. L. St. Aubin, France. Process and apparatus for treating coffee. January 22

4320 W. W. Nightingale. Manufacture of transparent ice. January 29

5162 H. Watkins. An improved baking powder. Feb. 16

10903 P. Jensen—From K. G. Duhl. Preserving milk, and vessels therefor. February 9

17075 C. S. Boynton and W. J. van Platten. Preparation of food products. February 9

1887.

122 H. F. von Konitz and J. Luntz. Manufacture of extract of coffee. February 5

B.—Sanitary Chemistry.

1886.

3826 J. G. Lorrain. Formation of organic oxides, and oxidation of matter suspended or dissolved in liquids. February 2

4878 W. F. B. Massey-Mainwaring. See Class I.

6331 A. Z. Germains. Apparatus for disinfecting, fumigating, etc. February 2

XVIII.—ELECTRO-CHEMISTRY.

APPLICATIONS.

881 F. H. Judson, London. An improved method of insulating the electrodes in electric batteries and forming the terminals thereof. January 20

925 J. Wodickz, London. Improvements in the inducing or magnetising parts of dynamo-electric machines and electromotors. January 20

990 S. W. Maquay, London. Improved means for feeding electric batteries and for removing the plates therefrom. January 21

1155 W. A. Phillips, London. Improvements in the manufacture of primary batteries. January 25

1333 W. Webster, jun. See Class XVII.—*B.*

1337 N. W. Perry, London. Improvements in galvanic cells. January 27

1390 R. C. Jackson, London. Improvements in dynamo-electric machines and electro-magnets. January 28

1595 W. Beissbarth, C. Fleischmann, and A. Beissbarth, London. Improvements in electrical batteries. February 1

1654 W. Kingsland, London. Closing or sealing secondary battery cells. February 2

1656 M. Bailey and J. Warner, London. Improved apparatus for preventing the escape of noxious fumes or other gases from primary, secondary, gas, or other batteries used for electrical purposes. Complete specification. February 2

1693 C. D. Abel, London—From La Compagnie Continentale Edison, France. Improvements in disc dynamo or magneto electric machines. February 2

1738 C. D. Abel, London—From Siemens and Halske, Germany. Improvements in dynamo-electric machines. Feb. 3

1741 O. Chauer and S. Rabay, London. Improvements in accumulators of electricity and in the manufacture of the same. February 3

1750 H. H. Lake, London—From Count R. de Montgelas, United States. Improvements relating to the electro deposition of aluminium and to apparatus therefor. Complete specification. February 3

1751 H. H. Lake—Count R. de Montgelas. Improvements relating to the extraction of aluminium from its chlorides, and to apparatus therefor. Complete specification. Feb. 3

1752 H. H. Lake—Count R. de Montgelas. Improvements relating to electric batteries. Complete specification. Feb. 3

1862 C. D. Abel, London—From A. Dun and F. Hasslacher, Germany. Secondary batteries. February 5

1929 C. D. Abel, London—From A. Dun and F. Hasslacher, Germany. Improvements in galvanic batteries. February 7

1982 G. E. Dorman, Stafford. Improvements relating to the transformation of heat into electricity by means of the thermopile.

1993 E. Hermite, J. Paterson, and C. F. Cooper, London. Apparatus for electrolysing bleaching solution. February 8

2028 P. John, Bristol. Improvements in electric batteries and containing vessels for liquids. February 9

2050 G. Wehr, London. Improvements in galvanic batteries. February 9

2134 A. Schanschieff, London. Improvements in galvanic batteries. February 10

2290 H. Leipmann, London. Improvements in the electrolytical treatment of ores for facilitating the extraction and recovery therefrom of gold, silver, or copper, and in apparatus therefor. February 15

2419 F. Bosshardt, London—From A. L. Hillaire-Desbois, France. Improvements in dynamo-electric machines. Feb. 16

2481 R. Marsh, Liverpool. Improvements in or appertaining to galvanic batteries and in electric connectors for other purposes. February 17

COMPLETE SPECIFICATIONS ACCEPTED.

1886.

2075 N. Tesla. Dynamo-electric machines. February 2

3183 T. A. Garrett. Improvements in dynamo-electric machines or motors. January 29

3475 R. E. B. Crompton. Dynamo-electric machines. Feb. 2

NOTICES.

Notice is hereby given that the next Annual General Meeting will be held in Manchester in the month of July, 1887, instead of in Glasgow as originally arranged; the Annual General Meeting in Glasgow being postponed until 1888.

This change originated in a generally-expressed desire, resulting in a special invitation from the Manchester Section, supported by the cordial acquiescence of the Glasgow Section. It will enable members to visit both the Royal Jubilee Exhibition in Manchester, and the Glasgow Exhibition of 1888.

Full particulars as to the Manchester Meeting will appear in a subsequent issue.

The supply of copies of the Journal for January, 1882, and January, 1883, being now exhausted, the Secretary would be glad to receive communications from members possessing extra copies of those numbers, in good condition, with a view to purchase.

Should sufficient applications for complete sets be received, the numbers will be reprinted.

Authors of communications read before the Society or any of its Local Sections are requested to take notice that, under Bye-Law 43, they cannot receive the prescribed 50 copies of their communications unless they comply with the condition laid down in that Bye-Law—viz., that they give notice of their desire to receive such copies upon their manuscript before sending it to the Editor. Mention should also be made as to whether the Discussion is to be included in the reprint.

CHANGES OF ADDRESS.

Capt. J. E. Bowly, l/o Birchfield; 51, Trinity Road, Aston Birmingham.

Thos. Christy, l/o Fenchurch Street; 25, Lime Street London, E.C.

A. S. Elmore, l/o London; Tweed Mill, Cockermouth.

N. Farrant, l/o St. Paul's Road; 2, Lawnside, Bearwood Road, Smethwick, Birmingham.

S. E. Field, l/o Nottingham; Thorpe End Brewery, Melton Mowbray.

H. C. D. France, l/o Edgbaston; Perry Hill, Quinton, near Birmingham.

W. Lawrence Gadd, l/o Manchester; Bank House, High Street, Wath-upon-Dearne.

Robt. Hamilton, l/o Muirkirk; Eglinton Ironworks, Kilwinning, N.B.

P. W. Harrison, l/o Peterboro'; 98, Queen Street, Exeter.

Thos. Kirkham, l/o Greenway Road; 22, Leinster Gardens, Runcorn.

B. E. R. Newlands, l/o Wanstead; 11, Dunsmure Road, Stamford Hill, N.

T. C. Panario, l/o St. Philip's Street; 18, Octavia Street, Battersea. S.W.

R. Preston, l/o Bury Ground; Fernsholme, Bury, Lancashire.

G. L. Rait, l/o Hampstead; 31, Moorgate Street, London, E.C.

S. Sellon; Journals, etc., to 3, Salters Hall Court, Cannon Street, London, E.C.

Dr. A. Senier, l/o Berlin; Thornfield, Harold Road, Upper Norwood, S.E.

H. Senier; Journals, etc., to 88, Norwood Road, London, S.E.

Jas. Towns, l/o Victoria Docks; 50, Morgan Street, Canning Town, E.

Wm. Windus, l/o Hughenden Road; 15, Vyvyan Terrace, Clifton, Bristol.

Jas. Wood, l/o Burnley; Whalley Abbey Printworks, near Blackburn.

CHANGES OF ADDRESS REQUIRED.

G. Bartholomew, l/o Windsor Road, Forest Gate, E.

T. Rowley, l/o 9, Conyngham Road, Victoria Park, Manchester.

LIST OF MEMBERS ELECTED, 23rd MARCH, 1887.

Wm. B. Andrew, Duntocher, Dumbartonshire, analytical chemist.

Peter T. Austen, New Brunswick, N.J., U.S.A., professor of chemistry.

A. E. Cobb, 77 and 78, Wellington Street, Woolwich, S.E., instructor in photography.

D. Colquhoun, c/o Chas. Tennant & Co., Limited, Carnoustie, N.B., manager of chemical works.

W. H. Cowburn, 3, Clarence Street, Albert Square, Manchester, drysalter.

Andrew Duncan, Dawsholm Gasworks, Maryhill, Glasgow, chemist.

Harold H. Everett, c/o The Borneo Co., Limited, 28, Fenchurch Street, E.C., mining engineer.

And. Ferrie, 79, Corporation Street, Manchester, chemical merchant.

Saml. S. Field, Eagle Villa, Westcombe Park, S.E., manager of chemical works.

D. Gamble, junr., Millbrook, Eccleston, Prescot, Lancashire, alkali manufacturer.

O. Herf, Main and Walnut Street, St. Louis, U.S.A., chemical manufacturer and merchant.

J. H. McArthur, Oakbank Oil Co., Limited, Midcalder, N.B., chemist.

Thos. Maxwell, Brownlee, Woodside Avenue, Rutherglen, Glasgow, manufacturing chemist.

Wm. Melland, c/o G. H. Milwood & Co., Bridge Street, Ardwick, Manchester, apprentice, calico printworks.

E. Ivens Moon, 85, Gracechurch Street, E.C., analyst, assistant to Mr. B. Redwood.

Benj. Nickels, junr., 13, St. Mary-at-Hill, E.C., analyst.

T. H. Norton, Ph.D.M.A., University of Cincinnati, Ohio, U.S.A., professor of chemistry.

Robt. Redwood, 85, Gracechurch Street, E.C., assistant secretary to Petroleum Association.

F. W. Smeaton, 53, Renfield Street, Glasgow, analytical chemist.

Chas. Smith, c/o Roxburgh Street Refining Co., Greenock, analytical chemist.

Chas. Spackman, c/o John Ellis & Sons, Barrow-on-Soar, Loughborough, Portland cement works manager.

Colin R. Strong, 18, Exchange Street, Manchester, oil merchant.

Henry Thomas, 41, Amberley Street, Sunderland (Redheugh Tar Products Co.).

Alex. E. Tucker, South Road, Smethwick, Birmingham, metallurgist.

W. F. Raphael Weldon, 11, Brookside, Cambridge.

Ernest Wheatcroft, 62, Page Hall Road, Sheffield, analytical chemist.

Deaths.

Geo. Atkinson, Aldersgate Chemical Works, Southall, Dec. 25th, 1886.

R. McKechnie, Thorndean, Elderslie, by Paisley, N.B.

London Section.

CHEMICAL SOCIETY'S ROOMS, BURLINGTON HOUSE.

Chairman: David Howard.

Committee:

Sir F. A. Abel.
H. E. Armstrong.
W. Lant Carpenter.
W. Crowder.
C. Graham.
S. Hall.
A. K. Huntington.

R. Messel.
B. E. R. Newlands.
B. Redwood.
T. Royle.
John Spiller.
G. C. Trewby.
J. Williams.

Hon. Local Sec. and Treasurer: Thos. Tyrer, Garden Wharf, Church Road, Battersea, S.W.

The meetings of the London Section will be held on the first Monday in each month.

SESSION 1886—87.

Prospective Arrangements.

April 1.—Discussion on Papers read 7th March.
,, Dr. J. M. H. Munro, "Further Notes and Experiments on the Composition and Manurial Value of Filter-pressed Sewage Sludge."
,, Mr. A. Wingham, "English-grown Tobacco," 2nd Part.
,, Triennial Election of Sectional Officers and Committee.
May 2.—Dr. P. F. Frankland, "Recent Bacteriological Research in connection with Water Supply."
,, Dr. C. R. A. Wright, "The Action of Zinc Chloride on Castor Oil."
June 6.—Dr. H. E. Armstrong, "The Alkaloids—the Present State of Knowledge concerning them, and the Method employed in their Investigation."
,, Mr. Boverton Redwood, "Notes of a Recent Visit to some of the Petroleum-producing Territories of the United States and Canada."
July.—Annual Meeting in Manchester.

Notices of Meetings and Papers will be found in the Scientific Journals.

Notices of papers and communications to be made to the Local Secretary.

Meeting held February 7, 1887.

THE PRESIDENT IN THE CHAIR.

DISCUSSION ON MR WINGHAM'S PAPER: "ENGLISH-GROWN TOBACCO" (SEE FEBRUARY NUMBER, PAGES 76—79).

THE CHAIRMAN said the subject was interesting, not only because of a possible new industry, but as a matter of agricultural chemistry. The very remarkable variations in the quantity of ash indicated by the author deserved careful attention. Undoubtedly they brought forcibly home to one's mind the fact that tobacco was an exhausting crop; for a vegetable product, with 25 per cent. of ash, required a very liberal provision of mineral constituents in the soil.

Dr. WRIGHT wished for information with respect to the alkaloidal constituents of English tobacco, and as to the percentage of nicotine compared with those of foreign tobaccos. A cigar, which would not burn and which contained no nitrates, did not seem to be quite a desirable article; but he presumed that by manuring with nitrates that difficulty might be overcome. Or possibly a good summer might mature the leaf so far as to render it capable of being actually used. With reference to the process of fermentation which took place, he presumed it involved quite a different series of changes from those discussed earlier in the evening (Mr. Jago's paper). He would like to know the condition of the English samples after undergoing that process; they would then be more fairly comparable with foreign growths. He did not wish to pry into the secrets of the trade; still, there were fearful whispers going about to the effect that tobacco leaves were often treated with ingredients of a character perhaps more natural than artificial. If the statements as to the liberal uses of molasses and urine in the manufacture of tobacco were true, he could well understand the reticence of the author on that part of the subject.

Mr. Mackinnon, having had considerable experience in the curing of tobacco, thought it might be useful if he gave a brief account of the process. It was on that process that the smoking qualities, and especially the "bouquet" of the leaf, entirely depended, and unless the curing were properly done, the finest grown tobacco would be absolutely worthless. The leaves were first dried in the shade, and were then dipped in a mixture consisting of the refuse of the crop and a small quantity of urine: this mixture being in a state of fermentation. After immersion in this liquid the leaves were laid flat on boards in large piles, and allowed to remain so until fermentation had proceeded sufficiently, which an expert workman could ascertain by the temperature on placing his hand between the layers. The piles were then undone, and the temperature reduced by exposing the leaves to the air. After a few days, however, the temperature rose again, when the process was repeated and the fermentation was considered complete. The leaves were then in proper condition for manufacture into cigars. He had seen this process carried out in both Cuba and Paraguay, and believed it was the plan used in most tobacco-growing countries. In Paraguay two classes of tobacco were produced, one being made from the lower leaves of the plant, which were plucked first: the other from the three or four leaves left at the top. This latter was considered the best tobacco, and was so excessively strong that he had been intoxicated by smoking a very small part of one cigar made from it. This effect was due to the large quantity of nicotine contained in that portion of the leaf, an effect to which the natives were so accustomed that they could smoke twenty such cigars a day.

Mr. Giles wished to know whether there was any foundation for the widespread opinion that tobacco prepared for smoking in pipes had of late been largely adulterated with glycerin and nitrobenzol. The effect of adding glycerin would obviously be to keep the tobacco moist and prevent loss of weight. The addition of nitrobenzol would, he supposed, give that peculiar flavour possessed by the class of tobacco called "honey-dew." That description of tobacco certainly emitted a smell akin to nitrobenzol, or artificial oil of bitter almonds. He considered the addition of glycerin very detrimental, as it produced effects irritating to the mouth and nasal organ of the smoker.

Mr. Crowder thought that a little ash, more or less, was quite consistent with a good cigar. Without the results of fermentation on the English leaf, one was quite unable to compare it with foreign tobacco. He did not think the proportion of lime or potash had much to do with the matter, but the proportion of nitrates was important. It was well known that tobacco curers frequently used a small quantity of nitrates, and if a little too much was added, the result was that the tobacco smoked unpleasantly "hot."

Mr. Bernard Dyer asked if the author had looked for lithium in the ashes. It had been laid down that lithium was a normal constituent of the tobacco plant, which was supposed to have a power of discovering and assimilating it. He was, therefore, curious to know whether these English plants had this constituent. He agreed that these ash analyses formed an interesting contribution to existing knowledge of the subject generally, though he must also agree with Mr. Crowder that they did not throw much light on the quality of the tobacco. The process of combustion and destructive distillation carried on in a good briar pipe was probably the only way of arriving at a satisfactory solution of that point.

Mr. Mumford hoped that the outcome of this paper and discussion would be to lead the English tobacco grower to pay more attention to the composition of his soil and the fertilisers necessary to grow a crop capable of competing with foreign tobaccos. Such a course would be productive of valuable results. He believed that abroad tobaccos were generally grown on very siliceous soils. Probably these English samples were grown on calcareous soil. He would like to know whether the potash had been used in the form of "muriate" of potash. That course had been tried abroad, and the result had been very deleterious to the quality of the tobacco produced.

Mr. J. Newlands wished to draw attention to a method of estimating ash which was not so widely known as it should be. In the usual method of proceeding, great difficulty was experienced in getting rid of the last traces of the carbon, on account of the fusion of the alkaline salts present. The substance should be fused in a muffle and allowed to cool; it should then be ground. Water sufficient to dissolve the salts should then be added, when they could be separated out by evaporation. The residue would calcine into a white ash without difficulty, and without the use of a very high temperature. This method of working had been found very useful in analysing sugar before the introduction of the French system.

A Member asked if the author would name the different species of tobacco cultivated (represented on the black-board by the figures 1, 2, 3, and 4).

Mr. Wingham, in reply, said his remarks had been brought forward with a view different from that assumed by the meeting. He had not pretended to lecture on the art of tobacco cultivation; consequently, he was hardly prepared to answer all the questions put to him. He had carried out his experiments from a chemico-industrial point of view, and with the object of showing British tobacco growers what to do and what to avoid—to point out the probable effect of different soils and different manures on a tobacco crop. He had endeavoured to estimate the nicotine in the unfermented English examples by Schlœsing's method—by digesting the leaves with ether, evaporating off the ether and ammonia, and estimating the residue with sulphuric acid. But when he came to titrate the solution, he had found it to be already acid, and so nicotine appeared to be absent. The question of nicotine, however, was not to be regarded as settled, as his experiments in that direction were not completed. With respect to the aroma of tobacco, said to be due to its oil, he did not believe that either nicotine or nicotianine existed in unfermented leaves, but thought that both those alkaloids were produced during fermentation. If his view were correct, the English leaves tested contained neither substance. It was well known that the percentage of nicotine in any tobacco was in inverse proportion to that of the nicotianine, and that the goodness of a tobacco depended on the percentage it contained of the latter—its essential oil. He had not analysed the oils that came off during heating. From what had been said, one would be inclined to think that urine was employed to start fermentation, but he did not believe it was so. The chlorine found in the English specimens had, of course, come from the soil. He did not think it within his province to enter into the question of the alleged sophistication of tobacco by nitrobenzol and glycerin. The idea of testing for lithium had occurred to him, but unfortunately too late to try it on the present samples. Mr. Mumford was quite right in thinking that the samples tested had been grown on a calcareous soil, and also in saying that a siliceous soil would be more advantageous. The quality of the tobacco depended more on the constitution of the soil than on its richness. He thanked Mr. Newlands for his suggestion: his own method had been to heat the tobacco at a very low temperature in a capacious platinum vessel inclined to one side. The examples of English grown tobacco treated were all American species—chiefly Kentuckian. There were really only three species of tobacco, but many varieties.

◆

FERMENTATION IN ITS RELATION TO BREAD MAKING.

BY WILLIAM JAGO, F.C.S., F.I.C.

Fermentation has been made the subject of careful and systematic study in connection with brewing and the production of alcoholic liquors generally; but, in its relation to bread making, has hitherto received but comparatively little attention from scientists. In many cases it has apparently been assumed that yeast behaves in just the same manner in dough as it does in a malt or other wort, and consequently that the same laws apply with equal force to the phenomena of fermentation in either substance. But the fermentation of wort differs from that of dough in several most important particulars. The former is a liquid, rich in maltose, and well adapted for the sustenance and growth of yeast; the latter is a stiff, elastic, semi-solid mass, containing but little readily fermentable matter. In wort, by a process of budding, yeast rapidly multiplies; but when added to dough the yeast cells show no signs of any reproduction by budding, but, on the contrary, gradually disappear, owing to the breaking-down of the cell-walls. In the fermentation of wort but a small proportion of the effect is due to the yeast originally added, the greater part being produced by the new yeast cells formed as the progeny of those first introduced; but in dough the whole of the work is thrown on the yeast cells primarily introduced into the mass. These are so unfavourably situated as to have little or no power of reproduction, and consequently on their activity and vitality successful fermentation must depend. This being the case, it is evident that mature and vigorous yeast is more absolutely essential to the baker than even to the brewer; since, if the latter's initial fermentation be sluggish, the progeny of new cells may fairly be expected to be more active. On the other hand, absolute freedom from foreign ferments is not a point of such vital importance to the baker as to the brewer. In many cases, a yeast that on microscopic examination would be immediately rejected by the brewer, would be found capable of making good bread. I might even go a step further, and say that of two yeasts the one deemed the better of the two, judging by purity as revealed by the microscope, might be the less desirable yeast for bread-making purposes. It is a well-recognised fact that in some varieties of bakers' barms the presence of other organisms than the yeast plant is normal. In particular, this is so with Scotch flour barms, which consist of yeast allowed to develop in what is essentially a thin paste made from scalded flour. This barm invariably contains the lactic ferment in large numbers. Mr. Thoms, F.R.M.S., a Scotch master baker, who has for very many years investigated yeast most exhaustively from the bakers' standpoint, is my authority for this statement. Mr. Thoms further informs me that on brewing flour barm at a sufficiently low temperature to prevent the development of *Bacterium Lactis*, the barm produced is inferior in quality, and yields an inferior loaf. It should be added that in bread made on the Scotch system there is always a distinct, though very slight, acid flavour. This acidity is altogether different in character from what is known as sourness of bread in the London district. The flavour of Scotch bread more resembles that wetted partly with butter-milk.

With healthy, active yeast cells, fermentation, as conducted in the South, proceeds sufficiently rapidly in dough to allow the bread to be completely ready for the oven before the lactic ferments have had time to develop any sensible acidity. In deciding as to the quality of yeast for bread-making purposes the first requisite is, that the yeast plant itself shall be in a vigorous and active condition. Among foreign ferments, the presence of those producing lactic acid at least is not deleterious in small numbers to anything like the extent that holds in the case of yeast to be used for beer brewing. Apart from their own specific action, foreign ferments are, in brewers' yeast, an evidence of carelessness and want of strict cleanliness in the yeast manufacture, and to this extent their presence may be interpreted unfavourably when judging the value of such a yeast for the baker. The point I hope I have made clear is, that if the yeast itself is healthy and vigorous, foreign ferments are not capable of doing the same amount of harm during the fermentation of dough, as during that of beer; principally because the act of baking the bread effectually destroys all fermentative action before disease ferments have had time to set up any injurious chemical change.

In passing, the aim of the baker in availing himself of the action of yeast during bread making may be explained. If the question were asked, Why is yeast employed? the answer in ninety-nine cases out of a hundred would be, to aërate the dough and thus make the bread spongy. Now yeast possesses this property in common with various other substances. There are, in fact, several ways of aërating bread more or less satisfactorily, but fermentation seems to be the only method capable of inducing other changes which are essential to the production of bread of the finest quality. By the action of yeast, the gluten, which contains the principal nitrogenous constituents of flour, is softened and mellowed, undergoing a species of digestive action, partly physical, inasmuch as it is rendered softer, and, probably, partly chemical, as a change analagous to peptonisation apparently occurs. Another most interesting effect of fermentation is, that it imparts a characteristic and pleasant flavour to bread, absolutely unattainable by other means. In bread aërated by any other method the results of these specific changes are absent; and public opinion decides that, after a time, such bread raised otherwise than by the action of yeast has a raw, uncooked taste, of which the palate speedily tires. Although the average baker knows nothing of the nature of the chemical changes induced by yeast, it is of great interest to note that his methods take cognisance of the fact that such changes are produced. If the production of sufficient gas to aërate the dough were his only object, then it might be expected that as soon as that object was attained he would proceed to get his bread in the oven. Such, however, is not the case; after a time, as much as possible of the gas generated in the dough is violently knocked out of it; this operation being sometimes repeated two or three times. The baker knows by experience that other changes which he desires to have take place will not be completed until some time after sufficient gas to aërate the bread has been developed. Theory and practice therefore both show that the aëration of the dough is only one out of several important effects produced by fermentation. From time to time, those interested in other methods of bread manufacture insist on the great loss caused by fermentation; thus, Dauglish expressed the opinion that this loss amounted to from 3 to 6 per cent., which opinion has since been adopted by Dr. Richardson, in his work on the "Healthy Manufacture of Bread." In order to determine the maximum amount of loss possible, I recently made the following experiment:—100 parts by weight of soft flour from English wheats were made into a slack dough with distilled water, two parts of pressed yeast being added, and no salt used. This dough was allowed to stand for from eight to nine hours at a temperature of about 85° to 90° F.; fermentation proceeded violently, but toward the end of the time had apparently ceased. The dough was next placed in the hot-water oven, and dried until of constant weight; the same weight of flour and yeast, unmixed, and without water, was also placed in the oven. At the end of the time, the fermented dough was found to have lost 2·5 per cent. compared with the flour. In this extreme case, a soft flour was used with distilled water and no salt, and about six times the normal amount of yeast; the temperature was purposely maintained at a high point, and the fermentation carried on so long as any decided evolution of gas occurred. Yet, under these conditions, which far and away exceed in severity any such as occur in practice, the loss was less than Dauglish's minimum estimate. The percentage of loss closely corresponds with that of sugar in flour as determined in a series of experiments to which I wish to direct your attention. Mr. Williams, a practical baker of high authority, estimates, from a series of experiments he conducted on the large scale, that the loss of solid constituents of flour during fermentation, as practically conducted in bakeries, amounts to 1·37 per cent.

Having for some time been engaged on an investigation of certain problems connected with panary fermentation, I take this opportunity of laying a synopsis of my results before you. In these experiments an apparatus of the following description was employed: a 12oz. bottle was connected with corks and tubing to a glass jar, graduated into cubic inches, so arranged that any gas evolved in the bottle entered the jar through the top. When in use the bottle was placed in a water-bath, maintained at any desired temperature by means of an automatic regulator. The graduated jar, which was open at the bottom, stood in a trough of water. At the commencement of each experiment the air was withdrawn from the jar until the water stood at zero. Carbon dioxide gas was thus collected over water, but when the gas does not bubble through the liquid the rate of absorption is comparatively slow. In some direct experiments I found it to proceed at the rate of about a cubic inch per hour. Allen states that saturated brine absorbs CO_2 but very slowly; I think only at about 15 per cent. of the speed with which water effects its absorption; brine might thus be advantageously substituted for water. As the experiments were made with the object of determining the relative amounts of gas evolved under different conditions, rather than the absolute quantity, no corrections were made for variations of temperature, pressure, or absorption of gas by the water. Errors from these sources would practically affect each member of a series of experiments made at the same time, to the same extent; and so would not disturb the comparisons between them. Further, the total possible error in most instances, would only be a small percentage on the total quantity of gas being evolved. As the apparatus employed was designed for the use of bakers, as a yeast-testing instrument, the units of quantity selected for the first experiments were the ounce and cubic inch; when smaller quantities were added on to these, in certain cases, these were weighed in grammes: hence there is rather an anomaly in the weights sometimes employed. At the start, duplicate experiments were made, in order to determine the degree of accuracy of the method. The following are the results of a pair of such duplicates:—

In each case there were taken: Brewers' yeast, ½oz.; sugar mixture, ½oz.; water, 6oz.; at 30° C. (The sugar mixture consisted of the dry constituent of "Pasteur's Fluid, with Sugar.")

These were mixed, placed in the bottle of the apparatus, which, in its turn, was placed in the bath at 30° C. The quantity of gas evolved was collected at the end of each half-hour; the following are the results of these readings:—

Time.	Gas evolved in cubic inches.	
0	0·0	0·0
½ hour	0·7	0·5
1 ,,	6·5	6·0
1½ hours	14·2	13·8
2 ,,	22·0	22·0
2½ ,,	30·0	29·7
3 ,,	41·0	41·0
3½ ,,	47·0	46·7
4 ,,	54·5	53·7

One of the earliest comparisons instituted was between filtered flour infusion, unboiled and boiled malt wort, and solution of "sugar mixture."

No. 1 solution consisted of 6oz. of 40 per cent. flour infusion (sp. gr. 1007·2), warmed to 30° C., and compressed yeast, ¼oz.

No. 2, 6oz. unboiled malt wort, same density.

No. 3, 6oz. boiled malt wort, same density.

No. 4, 6oz. sugar mixture solution, same density.

All started at the same temperature, and with the same amount of yeast:—

Time.	Gas evolved in cubic inches.			
	No. 1.	No. 2.	No. 3.	No. 4.
0 hours	0·0	0·0	0·0	0·0
1 ,,	2·2	6·5	7·5	12·0
2 ,,	5·2	14·4	15·9	22·4
3 ,,	6·5	16·3	17·8	21·1
4 ,,	7·4	17·0	18·2	24·3
5 ,,	8·3	17·1	18·2	24·3

It will be seen that the filtered flour infusion evolved gas far more slowly than did either the boiled worts or sugar mixture solution of the same density.

The next series of experiments was made with the object of determining the relative powers of supporting fermentation possessed by different constituents of flour. Chicandard has affirmed in the *Comptes Rendus*, May, 1883, that the fermentation of bread does not consist in the hydrolysis of starch, followed by alcoholic fermentation, and is not determined by *saccharomyces*, but is the result of the solution, and after peptonisation of the gluten, this effect being caused by a *bacterium*, which develops itself normally in the dough, yeast merely accelerating its development. One of the objects I had in view during the making of these particular experiments was the examination of this theory. The best plan will be to first state exactly the nature of each experiment, and then to refer to the conclusions to be drawn therefrom.

No. 1. 20 per cent. filtered infusion of flour, 6oz. (170grms.), at 30° C.; compressed yeast, ¼oz.

No. 2. 34grms. flour; water, 6oz., at 30° C.; compressed yeast, ¼oz.

No. 3. Washed insoluble residue from 34grms. of flour; water, 6oz. at 30° C.; compressed yeast, ¼oz.

No. 4. 20 per cent. filtered flour infusion, 6oz. at 30° C.; wheat starch, 5grms. taken and gelatinised, cooled, then added to flour infusion. Mixture placed in bottle and maintained at 30° C. for 12 hours; then ¼oz. compressed yeast added, and fermentation commenced.

No. 5. Moist, thoroughly-washed gluten, 5grms., triturated in mortar with sand, in order to expose large surface; gluten, with 6oz. of water at 30° C., placed in bottle and maintained at 30° C. for 12 hours; then ¼oz. compressed yeast added, and fermentation commenced.

No. 6. 20 per cent. filtered flour infusion, 6oz. at 30° C.; wheat starch, 5grms., gelatinised; compressed yeast, ¼oz.

No. 7. 20 per cent. filtered flour infusion, 6oz. at 30° C.; wheat starch, 5grms. ungelatinised; compressed yeast, ¼oz.

No. 8. Wheat starch, 5grms., gelatinised; water, 6oz. at 30° C.; compressed yeast, ¼oz.

No. 1, consisting of 20 per cent. flour infusion, gave off very little gas, the quantity amounting to only 3·3 cubic inches in eight hours. This is very much less than that obtained in the previous series of experiments in which a 40 per cent. infusion was employed; the latter gave off 8·3 cubic inches in five hours. No. 2, containing the whole of the flour, gave off gas much more copiously; in eight hours there being 19·6 cubic inches of gas evolved. After the second hour the evolution fell off slowly, but regularly. The washed residue gave off just the same amount of gas as did the filtered infusion; in fact, at the end of the fifth hour, No. 3 gave the higher reading. It will be noticed that the whole of the flour gives off three times as much gas as does the filtered infusion and the washed residue together. The reason is that, when flour is shaken with water and then filtered, the substances which, under the action of yeast, evolve gas, are not all removed in the filtrate. They consist in part of starch granules, in which the amylose is more or less exposed to the action of diastasic agents. With well washed and kneaded gluten but very little gas is evolved, the total amount in nine hours being only 1·5 cubic inches, and this, although the gluten for 12 hours previous to fermentation was digested with water at 30° C. In Nos. 4 and 6 the quantities used are the same, but the former of the two samples affords evidence of diastasis having been occasioned during the 12 hours for which the gelatinised starch was subjected to the action of the flour infusion. No. 6 at first proceeded somewhat the more rapidly, but evolved very little gas during the second hour. During the third, however, it recovered itself and proceeded regularly, until, at the expiration of six hours, the evolution of gas ceased, with a total of 33·7 inches. In No. 4 the fermentation proceeded rapidly and regularly, falling off towards the end, and finishing at five hours with 37·5 cubic inches. As a result of the previous diastasis, a large quantity of gas is evolved, but in each instance the greater part of the starch remained behind, as if 5grms. of starch were completely changed into sugar, and then, by fermentation, into carbon dioxide and alcohol. The yield of gas would roughly be about 85 cubic inches at 20° C. The diastasic action of the flour infusion will have more or less effected the hydrolysis of the starch into dextrin and maltose: the latter will have undergone fermentation, while the former is unfermentable. Experiment No. 8 shows that the diastasis of the starch is effected by the flour infusion, and not by the yeast; for where pure gelatinised starch and yeast alone are employed, exceedingly little gas is evolved; during eight hours but 1·2 cubic inches only having accumulated. This experiment was allowed to proceed overnight, and at the end of 21 hours 7·0 cubic inches had been evolved. Another reading was taken at the end of the twenty-second hour, and showed that 0·8 cubic inches had been evolved during the hour. It would seem that the diastasic action of yeast on pure starch increases somewhat after some hours, but within a limit of eight hours, which covers the time that flour is in most instances subjected to fermentation, little or no action has occurred. Very striking in connection with this is the result obtained in experiment No. 7, for when the ungelatinised starch was mixed with flour infusion and subjected to fermentation, 8·5 cubic inches of gas were obtained in eight hours. The flour infusion must, under these circumstances, have succeeded in hydrolysing some of the starch; for although starch is washed most carefully, there will always be a certain number of cells whose walls are sufficiently thin to permit diastasis to occur; and some investigators are of opinion that even unbroken wheat starch cells are comparatively readily attacked by hydrolysing agents. Summing up the results obtained in these experiments, it is found that:—

Filtered flour infusion supports fermentation slowly.

The frequently washed residue of flour supports fermentation at about the same rate.

The entire flour, mixed with water, evolves about six times as much gas as either the filtered infusion or the washed residue from the same weight.

Kneaded and washed gluten evolves practically no gas.

Flour infusion and gelatinised starch together evolve gas in considerable quantity.

The quantity of gas is increased when the infusion and the gelatinised starch remain together sometime before fermentation, which result is due to diastasis by the albuminoids of the infusion.

Ungelatinised starch, under the influence of yeast and flour infusion, evolves a moderately large quantity of gas.

Gelatinised starch alone undergoes little or no fermentation during a period of eight hours, but ferments slowly after standing some twenty hours.

In order to further determine the source of gas during the fermentation of flour infusion, the following experiments were made:—A 40 per cent. filtered infusion of stone-milled flour, from English wheat, was prepared by taking 600grms. of flour and 1500cc. of distilled water. These were several times shaken together during half-an-hour, and then allowed to subside. The upper layer of liquid was next poured off and filtered through washed calico. This was subsequently again filtered in the ordinary manner through paper until perfectly clear. On testing with iodine no colour was produced, thus showing the absence of both starch and erthyrodextrins. The specific gravity of the infusion was 1008·5, being somewhat higher than that of the 40 per cent. infusion used in a previous experiment. A portion of the infusion was tested for sugar before and after the inversion, and also for albuminoids. Six ounces of the infusion were then fermented with 25° C., with a quarter of an ounce of encore yeast. The experiment was continued for twenty-two hours, at the end of which time fermentation had entirely ceased. The clear liquid was then decanted off from the layer of yeast at the bottom, and tested for sugar and albuminoids, as was done in the separate portion of the original infusion. To the yeast remaining in bottle there was at once added half-an-ounce of sugar and six ounces of water at 25° C., and the testing apparatus set up and the quantity of gas evolved measured.

The sugar was estimated in the following manner:—A weighed quantity of the flour infusion was raised to the boiling-point, and maintained at that temperature for about five minutes, in order to coagulate albuminoids: the loss by evaporation was then made up by the addition of distilled water, and the solution filtered.

Quantities taken = 25cc. Fehling's solution.
50cc. water.
20cc. 40 per cent. flour solution.

Weight of cuprous oxide, Cu_2O, yielded = 0·1531grm. Assuming this precipitate to be due to maltose, then 0·1531 × 0·7758 = 0·1187grm. of maltose in 20cc. of the flour infusion = 1·48 per cent. of maltose in the flour.

In the next place, 50cc. of the flour infusion were taken, 5cc. of fuming hydrochloric acid added, and the solution inverted by being raised to 68° C. The acid was then neutralised by solid sodium carbonate, and the solution made up to 100cc. with water. This produced a 20 per cent. inverted solution.

Quantities taken = 25cc. Fehling's solution.
50cc. water.
20cc. 20 per cent. inverted flour infusion.

Weight of cuprous oxide, Cu_2O, yielded = 0·1860grm.

In 20cc. of a 40 per cent. solution there would be double this quantity = 0·1860 × 2 = 0·3720grm. From this must be deducted the amount of precipitate due to the maltose present.

0·3720 – 0·1531 = 0·2189grm. of Cu_2O due to a reducing sugar produced by inversion. Assuming this sugar to be cane sugar, or at least to have the same reducing power, then 0·2189 × 0·4791 = 0·1048grm. of cane sugar in 20cc. of the 40 per cent. infusion, = 1·31 per cent. of cane sugar in the flour.

The total sugar in the flour would thus be 2·79 per cent.

After fermentation, the upper liquid from the yeast bottle was also tested for sugars after filtration and coagulation of albuminoids as before. The uninverted solution gave no precipitate whatever with Fehling's solution. A portion was next inverted with acid in the manner already described. 20cc. of this solution gave a slight trace of precipitate with Fehling's solution, which was too little to weigh. So far, the practical result may be summed up in the statement that filtered aqueous flour infusion contains two or more varieties of sugar; these, during the act of fermentation, entirely disappear.

The infusion was tested for albuminoids by distillation with alkaline permanganate solution with the following results, calculated to the percentage present in the flour:—

In the infusion before fermentation ...... 0·76 per cent.
,, after ,, ... 0·78 ,,

Compared with analyses of other flours, the quantities are low. This is probably accounted for by a 40 per cent. infusion being made, whereas a 10 per cent. infusion is used in most analyses, the more dilute solution extracts the somewhat viscous albuminoids with greater readiness. The only deduction from these determinations is, that the amount of albuminoids in a filtered flour infusion is practically unchanged by the act of fermentation, there being no disappearance whatever of these bodies. The small increase observable is probably due to albuminous matter being yielded to the solution by yeast itself.

The following are the results of the fermentation experiments:—

No. 1. Flour infusion, 6oz.; encore yeast, ¼oz.: temperature, 25° C.
No. 2. Yeast from previous experiment after cessation of fermentation: Sugar, ½oz.; water, 6oz.; at 25° C.

As six ounces of the 40 per cent. flour infusion would contain the soluble matter of 68grms. of flour, it follows that there would be present, according to the analysis, 1·89grms. of sugar. This quantity, if entirely converted during fermentation into carbon dioxide and alcohol, would yield about 32 cubic inches of gas at 20° C. By the method adopted for testing, 15 cubic inches were registered at the end of twenty-two hours; to this would have to be added a correction for the amount lost by absorption by the water, in order to obtain a correct estimate. It is difficult, when the total quantity of gas evolved is small, to determine with accuracy the loss of absorption, because the gas in the apparatus consists of a mixture in which air is predominant, consequently the rate of absorption is less than with pure carbon dioxide gas. If it were desired to accurately estimate the quantity of gas, collection over mercury would have to be adopted. This is of little importance in the present experiment, because the total measured comes well within the amount of gas that the sugar would theoretically yield. In other words, there is no need to go outside the sugar to find a source from which the carbon dioxide is obtained, as the whole of the sugar disappears, and in the act of fermentation is capable of yielding more gas than that observed to be evolved. That the cessation of fermentation is not due to the exhaustion of the yeast is proved by experiment No. 2, in which the same yeast has more sugar added to it, when a vigorous fermentation was immediately set up. That the cessation of fermentation is due to the exhaustion of the sugar, is proved by that compound being absent on analysis of the infusion after fermentation. Summing up the whole of the results—

FLOUR INFUSION.

Before Fermentation.	*After Fermentation.*
Sugar, 1·89grms. in the six ounces of infusion.	Sugar, absent.
Albuminoids, 0·517grm. present.	Albuminoids, 0·530grm. present.
	When fermentation had ceased, 15 cubic inches of gas had been evolved, and the yeast was still unexhausted, and capable of inducing fermentation in fresh sugar solution.

Reasoning on these results, together with those obtained in the series of experiments on flour and its various constituents taken separately, the only logical conclusion is that the fermentation of dough is essentially a saccharine fermentation.

It may be demurred that the circumstances are different in an aqueous infusion to those which hold in a tough elastic mass such as dough. But it is inconceivable that the fermentation actually immediately depends on the conversion of any but soluble constituents of the flour into gas; therefore, if those albuminoids, so soluble as to pass through filter paper, are not capable of yielding gas as a result of fermentation by yeast, it follows that the more insoluble albuminous compounds likewise will not yield gas. The fact that washed gluten yield no gas affords corroborative proof of this point. (The small quantity actually obtained by experiment may be accounted for by the well-known difficulty of actually freeing gluten from all starchy and soluble matters.) That the fermentation of the flour itself yields several times more gas than does the filtered infusion, lends no support to the theory that it is the albuminous matter that is evolving gas, because it has been shown that pure ungelatinised starch causes a marked evolution of gas, being doubtless first converted into dextrin and maltose by diastasis. The fermentability of the washed residue is also accounted for by its containing starch. Supposing even that in dough, after fermentation had ceased, sugar as such existed, and could be removed and detected by analytic methods, that of itself would be no proof of the evolution of gas being at the expense of the albuminoids, or peptones derived therefrom (for the argument equally applies to these latter bodies), because simultaneously with the fermentation produced by the yeast there is a production of sugar by diastasis of the starch. Fermentation of sugar in a stiff dough is rough work for yeast cells, and it may well be that after a few hours they are thoroughly exhausted, and disappear through disruption of their cell walls; the continuance of diastasis would still cause the slow production of more or less sugar. Further, the diastasis of the starch must throughout fermentation *precede* its subsequent conversion into carbon dioxide and alcohol; and so, if the reaction be stopped at any point, more or less sugar would, as a rule, be found. Again, drawing a conclusion, the fermentation of dough is in part due to the fermentation of the sugar present, in part to the diastasis of a portion of the starch of the flour and its subsequent fermentation. These sources are sufficient, and more than sufficient, for the production of all the gas evolved: these statements admit of experimental proof. There is no satisfactory evidence in favour of the gas evolved being in any sensible degree derived from the albuminous constituents of dough. It should be noticed that no assertion is made that no gas whatever is derived from the albuminous constituents of flour; it is possible that in extreme cases gas is produced from albuminous matters as a result of butyric and putrefactive fermentations; but in ordinary bread-making, as it holds in the United Kingdom, the amount of gas derived from this source is of no importance compared with that from sugar, and indirectly from starch. Whatever amount of gas there is, that is thus obtained, is the result, not of the action of yeast, but of *bacteria*. Further, the statement that albuminous bodies do not themselves evolve gas during panary fermentation must not be construed into meaning that they do not affect the quantity evolved. In their capacity as nitrogenous yeast foods, they aid the yeast in its development, and consequently in its production of gas, by decomposition of saccharine bodies.

These experiments seem to me to effectually dispose of Chicandard's theory of the panary fermentation being due to the action of *bacteria* on the albuminoids of flour.

I feel that the time already occupied over this paper precludes my dealing any further with the problems involved in its title. I only venture to hope that my work may have proved of interest sufficient to justify my having thus occupied so large a portion of the valuable time of this Society.

DISCUSSION.

The CHAIRMAN said probably the most ancient of fermentations, after the fermentation of the grape, was that of bread. He would like to know whether Mr. Jago had made any experiments on the fermentation of leaven. It was a matter of importance and interest, especially in view of the bold assertion of the French author quoted by Mr. Jago.

Mr. A. WINGHAM wished to ask the author how, if the fermentation of bread were entirely saccharine in character, he accounted for that peculiar "mellowing" of the gluten, mentioned in the paper, which occurred during the fermentation.

Mr. F. ADAIR ROBERTS understood the author to say that fermentation by means of yeast possessed other advantages beyond the mere aëration of the bread. As there was a company doing a large trade in bread in London who, he believed, claimed that they aërated their bread by purely mechanical means, he would be glad to know what were the additional advantages of yeast fermentation over such mere mechanical aëration.

Mr. B. E. R. NEWLANDS remarked that the whole of the author's results seemed to depend on the quantity of carbonic acid measured under certain described conditions. The gas was collected over water, which of course absorbed a quantity of it, varying according to pressure, etc. It would be an easy thing to put a little oil on the water, and thus prevent the absorption of carbonic acid; or, better still, to use Dr. Scheibler's well-known apparatus. This apparatus would give results sufficiently accurate if allowance were made for temperature, etc.

Dr. WRIGHT wished to know whether the author had made any experiments with the object of determining the relative proportions of the supplementary products of bread fermentation, more particularly of the alcohol formed. He believed that some years ago a process was brought out for the condensation of the alcohol expelled during the operation of baking. He had been given to understand, however, that the chief results produced were the exhilaration of the workmen and the spoiling of sundry batches of bread in consequence. He wished to point out that the determination of the ratio between these supplementary products and the carbonic acid might yield some evidence as to how far the albuminoids underwent change and contributed to the final result.

Dr. **Squire**: I am interested to learn that the author considers the formation which takes place in bread is due to the action of yeast on saccharine matter, and not, as has been pretended, to the action of bacteria. The bacteria theory is by no means a new one. Every three or four months one finds in the *Journal of the Chemical Society* extracts from foreign journals describing some particular kind of bacterium to which bread fermentation is supposed to be due. Although the germs of these special organisms are supposed to exist on the corn from which the flour is made, they, for some reason or another, do not find their way into brewers' or distillers' worts. I entirely concur in the view that bread fermentation is due to the alcoholic fermentation of saccharine matter produced by diastatic action. Some two years ago I pointed out, in this room, that an unmalted corn (especially rye) contains a certain proportion of diastase. In some parts of Russia a good deal of spirit is made from raw rye, without the admixture of any malted grain, the unmalted rye containing sufficient diastase to effect a tolerably good conversion of the starch present. It is true that the produce of spirit is from 15 to 20 per cent. less than when malt is used, and that this process is going out of use; but it is a striking illustration of the presence of diastase in raw grain. I do not, however, agree with the author in thinking that the starch is acted upon by the diastase when the granules are whole. Brown and Heron found that whole granules of starch were quite untouched by malt infusion; but when the granules were ground up with sand, so as to break the granules, the starch was rapidly attacked by diastase. In the process of making flour, a certain proportion of the starch granules must get broken, and these would no doubt be sufficient to supply the saccharine matter required for the fermentation. I do not gather that sufficient attention has been paid, in the course of the author's experiments, to the influence of dilution. Very dilute saccharine solutions ferment with difficulty, and when the dilution is so great that the saccharine matter does not exceed 1 per cent. all fermentation ceases. I have never yet met with a case in which the whole of the maltose could be removed from a solution by means of fermentation, and I was therefore rather surprised to hear the author describe his fermented preparations as being entirely free from saccharine matter. There is very little doubt in my mind that the fermentation of bread is due simply to the action of yeast or maltose produced by diastase pre-existing in the grain, and not at all to the action of bacteria, except in the case of sour bread, the acidity being then due, no doubt, to bacteria. If bread fermentation were produced by bacteria, what is the use of adding yeast?

Mr. **John Heron** asked whether the author had found carbonic acid to be the only gas produced during the process of fermentation. That operation being carried on under considerable pressure, it seemed to him that having regard to the presence of soluble albuminous matters, other gases, such as nitrogen and hydrogen, would probably also be evolved. Therefore, in estimating the strength of the yeast, one ought, as far as possible, to put it under the same conditions as would hold in practical work in the bakehouse. It seemed that the fermentation of dough was carried on by certain species of saccharomyces. He had made several experiments on the fermentation of flour and other substances from cereals, comparing the ferments of flour with those of malt wort, and he had found that it was possible to isolate from the flour a ferment which was, so far as he could judge, saccharomyces *minor*. He regarded that organism as the most perfect form of ferment for bakers' use. But ordinary bakers' yeast contained a large variety of yeast cells, as well as various forms of bacteria, and he thought Mr. Jago would have obtained more useful and interesting results if he had experimented with this ordinary yeast taken from the bakehouse, rather than with the purer materials he had really selected. One probable result would have been to arrive at what was the best ferment with which to carry on the fermentation of bread.

Mr. **Jago**, in reply, said he thought the remarks which had been made bore out what he had said in the introduction to his paper, that fermentation in its relation to bread had as yet received but little attention. References had been made to points, of which the parallel points in beer brewing had been satisfactorily worked out, but which had not yet been touched in connection with bread. If he might alter the order in which some of these remarks had been made, he would like to refer to some of his experiments on the possibility of diastatic action on ungelatinised starch. The starch used was prepared by himself from a sample of the finest Hungarian flour—about the most perfect wheat starch obtainable. It was washed out by hand. The starch was then washed every day, until, at about the end of a fortnight, the washings gave no precipitate with Fehling's solution. Then it was carefully air dried at 40° C. He thought that was as representative a sample as one could get of starch, in the condition of consisting in the main of whole cells. In his opinion the process was really one of attack of the amylose through the walls of the cells. Whatever stage one commenced at there would always be, in a sample of starch, a percentage of walls with cells sufficiently thin to permit of diastasis occurring; for while cells in their most perfect condition were not susceptible to this agency, there would always be a number with walls sufficiently thin, by abrasion or "pitting," to permit of diastasis. With regard to the fermentation of leaven, he would refer those interested in the subject to a paper shortly to be read on it by Mr. W. A. Thoms. A copy of that paper should be sent to the secretary, and if it were thought that an abstract of it would be useful to the members he would undertake to supply one. As to the mellowness of the gluten, and how it was effected if the fermentation was essentially saccharine, it had been seen that one of the objects of his experiments had been the investigation of the evolution of gas; but some of his first statements had been pointed to show that fermentation had objects beyond that. He thought that the yeast cell, pure and simple, must have a diastatic action on the gluten and certain other constituents. If bread were aërated by any other means, there was an absence of that characteristic flavour which fermentation by yeast gave it. That was not merely an idea of his own, or of the men who made bread, but its truth was proved by the fact that bread aërated by other means never held the popular taste for long. It was the experience of practical men that such breads would sell well for a short time, but sooner or later the people came back to yeast made breads. In his opinion, yeast fermentation had the advantage, not only of producing a flavour more pleasing to the general taste than any other, but its employment induced a more or less digestive process of the nitrogenous constituents of the flour, rendering the bread itself more digestible as well as more tasty. He thought that there were good grounds for the complaint made as to the want of tables and diagrams to illustrate the paper, and, speaking for himself, he could only say *peccavi*. It would be a great improvement if papers could be printed and put in the hands of members at the meetings. Reference had been made to the fact that his experiments had depended on the evolution of carbonic acid, that carbonic acid being collected over water; and it had been suggested that he might have used a layer of oil over the water to prevent absorption. Well, he had tried an experiment that way with petroleum, and he had found that with an inch layer of petroleum over the water the absorption of gas was two or three times greater than when water only was used.

Mr. NEWLANDS asked whether the petroleum itself had absorbed the gas, and, if so, whether the author had tried vegetable oils.

Mr. JAGO replied that the petroleum had absorbed the CO_2, and at more than twice the rate of absorption by water. He had not tried vegetable oils. One of his reasons for making his experiments in the manner he had described was, that the apparatus was one which bakers could use themselves. A very large series of experiments were made, and all those of each series simultaneously and under the same conditions, so that whatever errors might occur would affect all equally. He had determined the relative quantity of alcohol in a few instances, but not systematically. He had not made any estimations with the direct object of ascertaining whether gases other than carbon dioxide were produced. That subject had been treated recently by M. Girard in the *Comptes Rendus* (101, 601—603), who found that the gas consisted mainly of carbon dioxide, mixed with the air originally contained in the flour. He had employed the yeast which was at present most commonly used by bakers—viz., compressed distillers' yeast. What was known as "patent yeast" often contained a large variety of ferments; brewers' yeast was much purer. But this compressed distillers' yeast was almost absolutely pure, and seldom contained any organism other than a saccharomyces, to which Pasteur had referred as "new high yeast," which, in his opinion, was the best for producing fermentation in dough. Brewers' yeast would ferment a pure saccharine liquid more rapidly than compressed distillers' yeast; but the latter would evolve gas at many times the rate of the former in a stiff dough.

Mr. HERON observed that what he had wished to draw attention to by his previous remarks was not so much the mere presence of foreign germs, as the fact that various yeasts were known to contain various species of organisms. There were different species of the *saccharomyces*, each one of which exercised a distinct specific function during fermentation. That was known to be the case in the fermentation of brewers' worts. It was, probably, also the case in the fermentation of dough, and, if so, one might expect that each particular class of ferment would produce its own peculiar effect on the flavour of the bread in which it was employed.

Mr. JAGO replied that he was now engaged in comparing the different kinds of ferments, and had a considerable mass of work done, which was, however, not sufficiently digested to be laid before the public. He was working on the whole of the varieties known commercially, and had already found several to produce distinctive and characteristic effects. He hoped in his present work to go a step further in the same direction, to isolate from each well-marked yeast the organism which characterised its specific action.

◆

Meeting held March 7, 1887.

THE PRESIDENT IN THE CHAIR.

M. HERMITE'S PROCESS OF ELECTROLYTIC BLEACHING.

BY C. F. CROSS AND E. J. BEVAN.

THE conditions under which bleaching powder has now for many years been produced are threatened with serious disturbance by the introduction of the ammonia-soda process. As a near relative of the now discredited Leblanc process, it will need to establish itself upon a new basis, a position independent of the particular complementary function which it has hitherto fulfilled. If it is assumed that bleaching powder, in its present form, is indispensable to chemical industry, its manufacture from lime and chlorine must be continued, and there will be a readjustment only in regard to the source of the hydrochloric acid, and the cost of production. But if, on the other hand, it can be shown that we have an altogether different source of supply of bleaching compound, similar, if not identical in nature and action, a new attack is opened, necessitating for its repulse a re-vindication, and on the ground of intrinsic superiority on whatever view we may take of the actual composition of bleaching powder—and from the later researches of O'Shea (*Chem. Soc.* 1883, 410), we may regard the formula proposed by Odling—viz., $Ca\genfrac{}{}{0pt}{}{OCl}{Cl}$ as sufficiently confirmed—the solution which it yields contains the hypochlorite $Ca(OCl)_2$, as the effective bleaching agent; and the reaction of this with the organic compounds, the consequent modification of which constitutes the actual bleaching operation, is one of simple oxidation. We may perhaps qualify this statement by the admission of certain cases in which chlorination or oxychlorination has been ascertained to take place, the products being chloroform or chlorinated derivatives of even higher molecular weight, but the fact is generally admitted that bleaching by means of the hypochlorites is, or may be, controlled, so as to be one of simple oxidation. The chlorine in bleaching powder we may regard, therefore, to borrow a term from electricians, as an *accumulator* of oxygen. From this point of view it is of interest to compare it with two other bleaching agents, very similar in their action, this action more obviously in either case depending upon a simple oxidation of the colouring matters which are removed or dislodged—viz., potassium permanganate and hydrogen peroxide, in the degree of concentration practically available.

The percentage ratio of active oxygen in these compounds is:—

Bleaching powder…………	$33 \underset{18}{\times} 71$	= 7·5
*Potassium permanganate	$\frac{O_3}{K_2Mn_2O_8}$	= 15·7
Hydrogen peroxide ………	(10 vols. 0)	= 1·4

Taking these substances at their selling prices of to-day, the advantages of bleaching powder in point of economy are sufficiently manifest. There are other advantages in regard to convenience and sim-

---

* The limit of deoxidation being taken as the dioxide.

plicity of application, but it is unnecessary to dwell in detail upon this superiority over all other generally known oxidising compounds. We have rather to contrast it in regard to results with compounds which have as yet been little studied; these are the products of electrolysis of solutions of the chlorides of the alkali and alkaline earth metals, more especially the latter. Viewing the matter *à priori* and generally, the first contrast which strikes us—assuming that by means of such electrolysis we can prepare a solution of similar nature and properties, containing—*i.e.*, a hypochlorite as the effective bleaching agent—is in the mode in which chemical energy is impressed, in the two cases.

Elementary chlorine and lime represent high potentials, of which some considerable fraction is dissipated in arriving at a *soluble* bleaching compound. The measure of the loss is the calcium chloride formed simultaneously with the hypochlorite in the solution. In the electrolytic process, on the other hand, we commence at the bottom of the scale of energy, as regards the material sphere of action, and, as we have reason to conclude, the energy practically of the current between the electrodes is impressed into the molecule rearrangement which is determined. The loss of energy sustained in the evolution of hydrogen is not a necessary one, at least in principle, for the gas can be collected and burned. Allowing this loss, however, it is, even if complete, considerably less than that represented by $CaCl_2$. But we shall find, in the results of measurements of oxidising efficiency in terms of the current, evidence of a retention of a portion of the hydrogen, and therefore of its energy, under the condition of the complicated hydrolysis which takes place. On this general forecast, which we now sum up, the electrolytic process offers a more economic disposal of energy in the production of effective combinations. It may be urged that our present method of preparing bleaching powder, and from this a bleaching solution, here contrasted with the electrolytic process, is capable of improvement, or even may come to be replaced by a process having for its basis the same chlorides, which shall be raised by purely chemical means to the necessary potential. Such a process, the theoretical complement of the Solvay alkali method, is no doubt an object of search to those engaged in its development, and we will not attempt to prejudge the probability of its success. The standard of to-day is bleaching powder as prepared by the well-known process, and to this all our comparisons must be referred.

In our comparison of the two systems on the ground of relative expenditure of energy in preparing the bleaching compounds, we have assumed that the products of electrolysis are likewise the corresponding hypochlorites. But, as we shall presently find, this is not the case. The electrolysis is, as already stated, of a complicated nature.

The heat of formation of magnesium chloride, which of all the chlorides has been found to give the best results, lies sufficiently near to that of water—

$$^{*}\ H_2O = 68{,}360 \qquad MgO.2(HCl) = 26{,}440 + 44{,}000 = 70{,}440$$

as to bring both within the range of the primary decomposing action of the current. The possible complications thus introduced, together with those of secondary decomposition and rearrangements, under the condition of a continuous influx of energy, render it impossible to predict the molecular equilibrium finally to be attained.

The electrolysis of water is, in itself, a complicated phenomenon, as the experiments and interpretations of De La Rive, Traube, and Jamezek sufficiently show (*Jahn. Elektrolyse*, p. 155). There is evidence of the decomposition of water into H and OH rather than into $H_2.O$. The presence of the halogens is known to affect very considerably the evolution of hydrogen; the halogen hydracids are formed at the cathode, and at once brought within the sphere of the electrolysis. Further, we know that the relations of the ions to the electrodes are in no sense invariable: on the contrary, they are entirely dependent upon the conditions of the electrolysis. In the special case we are considering it is conceivable that the chlorine at the anode will determine the translation of oxygen to the cathode. Again, the endothermic reactions $H_2O\ O = -23{\cdot}070$, $Cl_2.O = -18{,}040$ are so similar, in point of consumption of energy, that their simultaneous occurrence is highly probable.

These are a few of the causes of the extensive complications with which this electrolysis is attended.

What we may call the primary interpretation of an electrolysis, according to Faraday's law, presupposes a complete separation of the ions. When this does not occur, and where, by electrochemical substitution, the anode and cathode are brought into relationships peculiar to a peculiar balance of the products of analysis, the law requires a modified interpretation. We shall revert subsequently to this point, as affecting the particular case under consideration.

This decision is intended to prepare the way for two important experimental results, which have been so repeatedly verified, that we give them as inherently associated with this electrolysis. (*a*) The *bleaching* efficiency of the electrolysed solution is considerably in excess of that of a solution of calcium hypochlorite of the same *oxidising* efficiency, measured—*i.e.*, in terms of the usual standard—an alkaline solution of arsenious acid. (*b*) The oxidising efficiency—*i.e.*, free or active oxygen—thus measured and expressed in terms of the current, is in excess of that calculated on the basis of the electrolytic law, as directly interpreted.

It is necessary to give a short account of the probable causes underlying such important factors of the economy of the system. (*a*) In regard to the first, it is only necessary to state that the investigation of the electrolysed solution shows the presence of bleaching compounds of very high tension. Thus, on cooling to 0°, and shaking with ether at this temperature, even when the solution is, or is made, strongly basic, the latter exhausts a considerable proportion of the bleaching compounds, which evaporate for the most part spontaneously with the ether. The investigation of the composition of the bleaching solution is a complicated matter, and the results when complete will be dealt with in a future communication. For the present it is sufficient to state that, in addition to the hypochlorite, other compounds of high oxidising activity are present—viz., hydrogen peroxide, and probably a higher oxide of chlorine. The necessary result of this difference of composition is a difference in bleaching action: whether to the advantage of the electrolysed solution or otherwise we now proceed to consider.

Anticipating the statement of the results of experiments as to the comparative bleaching efficiency of the two solutions—ordinary bleaching powder and electrolysed magnesium chloride—at equal oxidising strength, the superiority of the latter has been incontestably proved, the relative bleaching efficiency having been found in many cases 1 : 2. Keeping, for the present, to *à priori* view of the matter, have we any theoretical ground for regarding such a

---

* Neglecting considerations due to changes of state.

result as improbable? The bleaching of vegetable fibres is, or is the result of an oxidation, and from the similarity of the substance decolourised by the oxidation to the mass of the fibre substance, which is, to use the ordinary expression, bleached, it may be concluded that the oxidation is not limited simply to the decolourising of adventitious constituents, but is extended to the whole fibre substance. This is, moreover, abundantly proved by experiment. Such an action differential in character implies, in itself, a variable consumption of oxygen. But the study of the particular characteristics of the fibre constituents increase still further the probability of such variation. The oxidation of aldehydic molecules, already in a complex condition of condensation, is attended by water exchanges, which may be, in the one or other direction—*i.e.*, of hydrolysis or condensation. Time, in this view, is an important factor; rapidity of attack will favour the former, and *vice versâ*. Further, it is evident that the greater or less activity or tension of the oxygen in bleaching compounds would determine corresponding variations in the mode of attack, and the bleaching, with its attendant changes, would be similarly influenced, both in direction, and, as we may reasonably infer, in consumption of oxygen. Our experience of bleaching in the Mather-Thompson continuous range has abundantly proved the importance of rapidity in the first attack, and that this rapidity is characteristic of compounds of high oxygen tension. A long series of experiments with the electrolysed solution, also containing such compounds, have been attended uniformly with the two results (1) rapidity of action, and (2) small consumption of bleaching oxygen, comparatively with bleaching powder solution, and we are driven to conclude that these two results are essentially correlated.

The former result we are able to demonstrate by experiment here; for the latter, not conveniently admitting of demonstration to an audience, we have the evidence of a large number of determinations, in which the various vegetable fibrous substances known to commerce have been treated. Of these we shall cite typical experiments—we defer the consideration of these until we have considered more closely the quantitative aspect of the electrolysis, and the special features mentioned under (B).

For the measure of the current the usual units are, of course, adopted, and for the chemical effect we take the aggregate measure of oxidising effect, as determined by titration with arsenious acid, and expressed for convenience of comparison with bleaching powder in terms of the active or available chlorine. The solution, which it has been found most advantageous to use, contains 2·5 per cent. of $MgCl_2$, anhydrous. A tank, such as is used in installations of the Hermite system on the large scale, was filled with 845 litres of the above solution at the ordinary temperature.

A mean current of 200 ampères was passed for 12 hours; the titrations of the liquid and instrument readings were performed every 15 minutes.

The mean yield of the available chlorine per ampère hour, and the accumulation or quantity per litre, are given below, the experiment being considered divided into four successive periods of 3 hours each:

	Cl. per Ampère Hour.
1 period	1·80grms.
* 2 „	1·12 „
3 „	1·56 „
4 „	1·40 „

The equivalent calculated according to the electrolytic law is $1·05 \cdot 10^{-5} \times 60 \times 60 \times 35·5 = 1·34$grms.

The explanation of this apparent divergence from the theoretical number follows from what he gave before. The theoretical electrochemical equivalents we take to be the quantities separated at the one or other electrode in electrolyses which are ascertained to be simple, and which are worked by a sharp separation of the ions; in other cases, such as the present, where the work of both electrodes, so to speak, appears in the aggregate result, which is arbitrarily measured as an aggregate, and in terms of a particular effect, as the measurement is not in accordance with the law, so the result is in no sense a divergence from the law. Taking the mean number 1·47 available chlorine per ampère hour thus accounted for, we will express it in terms of mechanical work expended to produce it—5 "Watts" being equal to 1·47Cl (the em.f. being taken at 5 volts); the production of 100kilos. Cl will consume 344,000 Watts. Taking 600 Watts at the dynamo pulley as representing h.p. effective—and this equivalent has been supplied to us by our friend Prof. Pictet, as the result of a very large number of careful determinations—we see that to produce 100kilos. chlorine per hour we require the motive power represented by 570h.p. This we may call the fundamental industrial equation—the expression of mechanical work in terms of the chemical effect which it produces.

The equation, however, is not yet in its final terms, for, as already indicated, the term "available chlorine" and all that it implies, is a purely arbitrary one, and we have yet to examine into the relative bleaching efficiency of the electrolysed and bleaching powder solution, at equal oxidising strengths on the arsenite standard.

Assuming for the moment that they are equal, the bleaching powder equivalent is 300kilos. = 6cwt. per hour, with a plant representing 570h.p.

Further, we have taken the power at the dynamo pulley; consequently we have to take into account, in a complete statement of relative cost, the special apparatus necessary for the electrolysis. This we shall defer until we have dealt with the previous question.

We may mention that the above measurements were made in conjunction with Professor Pictet, who has recently devoted some days to the minute study of the process as applicable with his system of preparing wood pulp by digestion with aqueous sulphurous acid. He fully confirms the results obtained by us in our first investigation, which we undertook at the request of M. Hermite, the inventor, and Messrs Paterson and Cooper, the joint proprietors of the process and patents upon which it is based. M. Hermite, or rather his system, having been subjected to certain damaging, but ill-founded, criticisms in an English technical journal, he thought it expedient to ask us for an independent judgment on the necessary basis of actual measurement. Our results are given in two reports which, although private communications, are printed, and are available to any who may wish to go more into detail than it is possible or advisable to do in this paper. Further, the measurements were made on the laboratory scale, our model tanks containing only some 12 litres of solution, and, as we said, concluding our report speaking of the defects of the apparatus and their influence on the results, "these defects, which are chiefly those of arrangement of apparatus, are already obviated in the apparatus designed for working on the large scale, and we look with confidence to an ample verification of our estimate when the apparatus comes to be worked on the manufacturing scale."

---

* Milk of lime added to basic reaction; yield consequently diminished.

In other words, it was obvious that the mean number which we then obtained for yield of "available chlorine"—viz., 1·25grms. per ampère hour, was a minimum. The superior conditions under which the current is disposed, the arrangement of the electrodes, the circulation of the liquid, and, what is more important, the altogether different balance of products determined by the large mass of solution—these modifications have very considerably raised the ratio of oxidising efficiency to the current.

The results obtained with calcium chloride, to which we will devote a few words in concluding this part of our subject, are not so favourable as with the magnesium compound. It is not surprising that a complicated electrolysis, attended by a sensitive balance of products, should be affected by a change of base. The thermochemical constants for the calcium salts are different, and the atomic weight of the metal is nearly double. The investigation of the difference in the electrolysis is an elaborate problem; at the same time, the differentiation consequent upon the alteration of the basis is a considerable facilitation of the work in the scientific sense, and whatever the industrial outcome, upon which we reserve our opinion, the interest and importance of the problems are intrinsically great.

The comparison will also be required to be made on the large scale, for we have seen how the volume or more of the solution electrolysed affects the final equilibrium. Fully alive as are the proprietors, and as we need scarcely say the inventor, to the close union of science and industry, the laboratory which they have constructed for the purposes of these investigations promises to contribute in the future considerably to both. Sufficient unto the day are the results thereof—in fact, there is no occasion to anticipate, and therefore pass on from this discussion of the electrolysis to that of its application to bleaching purposes.

In all the usual modes of employing bleaching powder, the basis is that of exhausting, as far as possible, the active constituents of the bleaching solution, the exhausted solution being then ejected. It is probable, on the grounds previously discussed, that if the strength of the solution were prevented from falling by the addition of hypochlorite *pari passu* with its consumption, the actual consumption would be less as the time required certainly would be. The difficulties and waste attending such a system, however, would probably outweigh the advantages, and so we can adopt the present empirical method as representing the economic mean attained by crude practices. An important feature of M. Hermite's system is that the maintenance of a certain minimum of bleaching strength is perfectly under control.

The principle of the method is the circulation of the bleaching liquid, from the electrolytic tank, of course of special construction, through the bleaching tank, which may be any of the forms ordinarily used. By means of the current, therefore, a continuous supply of the bleaching compounds can be kept up, and the bleaching rendered more economical in regard to consumption of "chlorine" as well as much more rapid. In our comparative estimate of bleaching efficiency we propose to leave the time factor out of consideration, basing our comparison only on the relative consumption of chlorine.

Of all the numerous bleaching operations in the domain of vegetable fibres, the greatest consumption of bleaching powder is found in the treatment of linen yarns (20—40 per cent.) and paper pulp (10—25 per cent.); of the latter the maximum consumption takes place in the bleaching of straw, esparto, and bisulphite wood pulp.

In both departments we have made a large number of comparative determinations, of which we will cite typical results:—

Flax yarn.—(*a*) Three-quarter bleach on *boiled yarn*:

Two *dips* with intermediate scald in soda ash:

Weight of Yarn.	Electrolytic Cl. consumed.	Chlorine as Bleaching Powder.
330grms.	1 dip .. 12·3 2 " .. 2·3 Total 14·6	29·2

The electrolytic chlorine, therefore, has double the efficiency of the chlorine of bleaching powder.

(*b*) Three-quarter bleach from *green yarn*, two dips with intermediate scald in soda:—

Weights of Yarn.	Electrolytic Cl. consumed.
372grms.	13·75+7·45=21·2

This result could not be attained with bleaching powder similarly employed; a further treatment, consisting of a scald and dip being necessary.

Multiplying the 21·2 of Cl by 3, we get what we may consider as the equivalent weight of bleaching powder—*i.e.*, 20 per cent. on the weight of the yarn. To produce the same result with actual bleaching powder, the consumption was 38 per cent. The result, therefore, is as in the preceding.

We may sum up our experimental results in this province as follows:—On the electrolytic system the consumption of chlorine is one-half that on the ordinary system; owing to the greater efficiency of the bleaching, we are able, in certain grades of bleaching, to suppress one or more of the alkaline treatments, in which case the loss of weight sustained by the yarn is less; in all other respects the results on the two systems are very similar.

Paper Pulp.—The various classes of pulps enumerated above, requiring for a full bleach from 18—25 per cent. of bleaching powder, calculated in the weight of the product, have been bleached in the electrolytic system under a great variety of conditions, and in a strict comparison of the two systems. The consumption of electrolytic chlorine we have always found to fall within the limits of 3—5 per cent., or multiplied by 3, to obtain the assumed equivalence of bleaching powder, 9 to 15 per cent.

We do not propose to enter into further details in regard to these comparisons. We approached the matter ourselves with a reasonable amount of scepticism and sufficient experience of the ordinary systems of bleaching to prevent our falling into any considerable error in the investigation. We give these conclusions as our confirmation of Mr. Hermite's figures; and, as he is fully disposed to give to others, as he has to us, the facilities for verifying by experiment all the quantities upon which his system, as an industrial one, is based, we have the less need to occupy space with details of measurements.

We revert now to what we called the fundamental equation of economy. Instead of taking an equal value for chlorine in the two forms, we will take the ratio 3 : 5 as the mean of our various determinations, for the efficiency of the chlorine of bleaching powder, to that of the electrolysed solution. Therefore, the mechanical work represented by 570h.p. will produce the equivalent of 10cwt. of bleaching powder per hour, or, expressed in a more convenient form, a 50h.p. engine will give 1 ton per day of 24 hours. Taking the cost of 1h.p. (steam) at £9 per annum, and calculating the output on the basis of 300 working days, the cost for power is £1 10s. per ton of the hypothetical product. In cases where water power is available, the costs, of course, will be considerably less. We have taken, for convenience, what may be considered a fair average cost of mechanical effect, leaving special cases to be specially dealt with. We now have to consider the cost of the special apparatus, dynamo, tank, electrodes, and leads. For a current of 1000 ampère at 5 volts., the unit installation as we may permit—this amounts to £350; each such unit giving us the equivalent of $\frac{1}{6}$ ton of bleaching powder—1000 (current) × 1·40 (yield per A.H.) × 5 (eqt. bleach powder) × 24 = 168,000grms. in the 24 hours—we should require 6 such units to use up the work of the 50h.p. machine. Taking 15 per cent. on the capital sum for interest and depreciation, it amounts to £1 per ton of hypothetical bleaching powder.*

The only other important item of cost is the salt, magnesium chloride. The waste of this can be arrived at on the basis that a drained pulp will retain as a maximum twice its weight of water, or in this case a 2½ per cent. solution of $MgCl_2$. The waste will be, therefore, 5 per cent. on the weight of the pulp bleached, which is 1 per cent. on the hypothetical bleaching powder—in any case a very small amount in money value.

We are dealing with money values, not from the merely commercial point of view—*i.e.*, as a question of advantage to this or that manufacturer, but from the point of view from which we started—viz., the probable future of bleaching powder; and having worked our way round to this question, we leave it as it is always most satisfactory to do, unanswered.

We do not anticipate any panic amongst bleaching-powder manufacturers, nor do we venture to propose that another of the "noxious trades" should henceforth be regarded as doomed. We only ask for the indulgent consideration of results which appear to us to have an important bearing on the chemical industry of this country.

In conclusion, we should like to express our obligation to the inventor, M. Hermite, and those who are associated with him, for the opportunity afforded to us of laying this matter, full as it is of scientific interest, before the Society.

◆

Meeting held March 7, 1887.

THE PRESIDENT IN THE CHAIR.

"CASTNER'S SODIUM PROCESS."

BY JAMES MACTEAR, F.C.S., F.I.C.

Having been for some months professionally engaged in connection with the development of the Castner sodium process, I am enabled, through the kind permission of Mr. Castner, to present to this Society the details of his process for producing the metals, sodium and potassium, together with a few facts concerning their uses and the cost of manufacture.

The process, heretofore exclusively used for the production of these two metals, is so well known, that anything more than a brief reference to it is hardly necessary in this paper.

By the older process, carbonate of soda, charcoal, and lime, in the proportion of 30, 13, and 7, are made into the finest and most intimate mixture, and then calcined at a red heat to render the mixture more compact, which also expels a considerable amount of carbonic oxide. This calcined mixture is then introduced into wrought iron cylinders of small diameter, and heated to a temperature of about 1400° C., whereby the alkaline metal is reduced and distilled from the cylinder, through a small tube provided for the gases and vapours, into the receptacle known as the condenser. Through a variety of causes, not more than 40 per cent. of the metal contained in the charge is obtained, and in the manufacture of potassium very much less. The tear and wear on the metal cylinders is enormous, and forms a large proportion of the cost of manufacture. To carry out this process and arrive even at these results require:—1st, the most careful grinding and mixing of ingredients; 2nd, the addition of lime to prevent fusion; 3rd, an excess of carbon to ensure contact between the particles of soda and carbon in the refractory charge; 4th, previous calcination to make the charge less bulky; 5th, wrought iron must be used in constructing the cylinders, being the only metal which it is practicable to use that will stand the high temperature; 6th, cylinders must be used of small diameter, so as to allow the heat to penetrate to the centre of the refractory charge; 7th, the exit tubes from the cylinders to the condensers require the most careful attention to keep them open, owing to the formation of the black compound, formed by the action of carbonic oxide upon the vapour of the alkaline metal, which combination takes place at about the condensing point of the metallic vapour. This is one of the most serious obstacles to be met with in the course of manufacturing sodium or potassium, not only causing a large loss of metal, but interfering generally with the operation. In the making of potassium the formation of this compound, which is exceedingly explosive, and which is produced even more readily than when making sodium, is the chief reason that this metal costs almost ten times as much as the same quantity of sodium.

As near as I can ascertain at present, sodium costs about 4s. per pound to produce, the following being the chief items:—

Wear and tear to furnaces, cylinders, etc.	2s.
Materials owing to loss and waste	1s.
Labour	8d.
Fuel	4d.

Since Mr. Castner's paper upon his process, which was read before the Franklin Institute of Philadelphia, October 12, 1886, several slight changes in the mode of carrying on the process have been made. These have been brought about by the experience gained from the actual working of the process upon a commercially large scale.

The reactions by which sodium and potassium are produced are somewhat difficult to describe, as they vary somewhat according to the mixture of materials and temperature employed in the reduction. The mixtures which it is now preferred to use, are represented by the reactions:—

$$(1.)\ 6NaHO + FeC_2 = 2Na_2CO_3 + 6H + Fe + 2Na;$$

$$(2.)\ 6KHO + FeC_2 = 2K_2CO_3 + 6H + Fe + 2K.$$

In place of using an actual chemical compound of iron and carbon, as expressed by the above reaction, a substitute or equivalent is prepared as follows:—To a given quantity of melted pitch is added a definite proportion of iron in a fine state of division. This mixture is cooled, broken up into lumps, and coked in large crucibles, giving a metallic coke consisting of carbon and iron, the proportions of each depending upon the relative quantities of pitch and iron used. This metallic coke, after being finely ground, provides a substance having the iron and carbon in a like proportion to an iron carbide, and from which neither the iron nor carbon can be separated by mechanical means. The fine iron is conveniently prepared by passing carbonic oxide and hydrogen in a heated state, as obtained from an

---

* In those countries where the position of bleaching powder is different, the economic basis of comparison will be different. In the majority of cases the result would be found to be even more favourable to the electrolytic system.

ordinary gas producer, over a mass of oxide of iron, commercially known as "purple ore," heated to a temperature of about 500° C.

In producing sodium, preferably of the highest obtainable strength, caustic soda is mixed with a weighed quantity of the so-called "carbide," sufficient to furnish the proper amount of carbon to carry out the reaction indicated above. The crucibles in which this mixture is treated are made of cast steel, and are capable of containing a charge of 15lb. of caustic soda, together with the proper proportion of the carbide.

After charging a crucible with the above mixture, it is placed in a small furnace, where it is kept at a low heat for about 30 minutes, during which time the mass fuses, boils violently, and a large part of the hydrogen is expelled by the combined action of the iron and carbon; the carbide, owing to its gravity, remaining in suspension throughout the fused soda. At the end of the time stated, the contents of the crucible have subsided to a quiet fusion. The crucible is then lifted by a pair of tongs on wheels, and placed upon the platform of the elevating gear, as shown in the drawing, and raised to its position in the chamber of the main distilling furnace. The cover, which remains stationary in the furnace, has convex edges, while the crucible has a groove round the edge, into which the cover fits. A little powdered lime is placed in the crucible groove just before it is raised, so that when the edges of the cover and crucible come together, they form a tight joint, and, at the same time, allow the crucible to be lowered easily from the chamber when the operation is finished, to give place to another containing a fresh charge. From the cover projects a slanting tube (as shown) connected with the condenser. The condenser is provided with a small opening at the further end, to allow the escape of hydrogen, and has also a rod fixed (as shown), by means of which any obstruction which may form in the tube, during distillation, may be removed. After raising a crucible into its place in the furnace, the hydrogen, escaping from the condenser, is lighted, and serves to show, by the size of the flame, how the operation is progressing in the crucible, the sodium actually distilling soon after the crucible is in its place. The temperature of the reduction and distillation has been found to be about 823° C. The gas coming off during the first part of the distillation has been analysed, and found to consist of pure hydrogen. An analysis of a sample of the gas, taken when the operation was almost completed, gave, as a result, hydrogen 95 per cent, carbonic oxide 5 per cent. It has been found advisable to use a little more carbide than the reaction absolutely requires, and this accounts for the presence of the small quantity of carbonic oxide in the escaping gas, the free carbon acting upon the carbonate formed by the reaction, thus giving off carbonic oxide, and leaving a very small percentage of the residue in the form of peroxide of sodium. This small amount of carbonic oxide rarely combines with any of the sodium in the tube; and so the metal obtained in the condensers is pure, and the tubes never become choked with the black compound. In the preparation of potassium a little less carbide is used than the reaction requires; thus, no carbonic oxide is given off, and all danger attached to the making of potassium is removed. After the reduction and distillation, the crucible is lowered from the furnace, and the contents poured out, leaving the crucible ready to be re-charged. The average analysis of the residues show their composition to be as follows:—

Carbonate of soda	77	per cent.
Peroxide of sodium	2	,,
Carbon	2	,,
Iron	19	,,

The average weight of these residues from operating upon charges of 15lb. caustic soda, and 5¼lb. of carbide, is 16lb. These residues are treated either to produce pure crystallised carbonate of soda or caustic soda, and the iron is recovered and used again with pitch in the formation of carbide. From this residue, weighing 16lb., is obtained 13lb. of anhydrous carbonate of soda, equivalent to 9·4lb. caustic soda, of 76 per cent.

Operating upon charges above mentioned, the yield has been—

Sodium ....actual	2·50lb.	Theory..	2·85lb.
Sodic carbonate .. ,,	13·00lb.	,,	..13·25lb.

The average time of distillation in the large furnace has been 1 hour and 30 minutes, and as the furnace is arranged for 3 crucibles, 45lb. of caustic soda are treated every 90 minutes, producing 7½lb. of sodium and 39lb. of carbonate of soda. The furnace is capable of treating 720lb. of caustic soda daily, giving a yield, in 24 hours, of 120lb. of sodium and 624lb. of anhydrous carbonate of soda. The furnace is heated by gas, which is supplied by a Wilson gas producer, consuming 1cwt. of fuel per hour. The small furnace in which the crucibles are first heated requires about ½cwt. per hour. The following estimate of cost, etc., is given from the actual running of the furnace working with the above charges for 24 hours.

	£	s.	d.
720lb. of caustic soda at £11 per ton	3	10	10
150lb. carbide at ½d. per lb.	0	6	4
Labour	1	0	0
Fuel	0	17	0
Re-converting 624lb. of carbonate into caustic, at a cost of about £5 per ton on the caustic produced	1	0	0
Total	6	14	2
Deducting value of 475lb. of caustic recovered	2	6	8
Cost of 120lb. of sodium	4	7	6
Cost per pound	0	0	8¾

Regarding the item of cost for damage to the crucibles by the heat, this question has been very carefully gone into. Some of the crucibles have been used upwards of 50 times, and from their condition at the present time, there is no doubt that they can continue to be used at least 150 times more before they become unfit for further use. In considering 200 operations to be the life of a crucible, the item of damage or wear and tear amounts to less than 1d. per pound on the sodium produced; and, if we take the furnace wear and tear at the same rate of 1d. per pound, we shall see that the wear and tear of plant is only 1/12th of that incurred in the ordinary process. *It is upon these facts that Mr. Castner bases his claim to be able to produce sodium by his process upon the large scale, at a cost of less than 1s. per pound.* The advantages of this process will be apparent to any one at all familiar with the manufacture of these metals as conducted heretofore. The first and most important end gained is their cheap production, and this is owing chiefly to the low heat at which the metals are produced, the quickness of the operation, non clogging of the conveying tubes, and a very small waste of materials. The process, furthermore, admits of being carried on upon a very large scale; in fact, it is intended ultimately to increase the size of the crucibles, so as to make the charges consist of 50lb. of caustic soda. Crucibles of cast iron have been found quite suitable; and it is intended, in future, to use crucibles made of this material in place of the more expensive steel.

As regards potassium, it has hitherto been regarded very much as a chemical curiosity, and sells for about 60s. per pound. By this method the cost of the manufacturing operations is no more than for sodium, the higher cost of the caustic potash being the chief element of increased expense. The uses of these alkali metals are at present limited, owing to their high cost alone. Sodium is used somewhat largely in manufacturing aluminium, magnesium, silicon, etc., and in the formation of amalgams, while potassium is only used in small quantities as a chemical magnet. It will hardly be considered out of place in concluding this paper, relating to the manufacture of sodium and potassium, to mention some few facts connected with aluminium. This metal depends at present upon sodium for its production, and, consequently, any process successfully producing *cheap* sodium, in reality allows of the manufacture of *cheap* aluminium. Notwithstanding all the efforts that have been made by various chemists and metallurgists for the past thirty years in endeavouring to invent some process for producing aluminium, whereby that most interesting and valuable metal could be cheaply produced by a better process than that of Deville, absolutely nothing has been accomplished that would even lead one to hope that some time in the future his process would be superseded. By employing Deville's process, and using sodium as heretofore manufactured, the aluminium costs between 30s. and 40s. per pound. Owing to this high price alone, the consumption is limited, and therefore the manufacturer is obliged to ask, in selling the metal, a relatively high price, in order to obtain anything like a fair profit upon the invested capital. The present selling price of aluminium varies between 50s. and 60s. per pound: although every few months there appears in some newspaper the information that some parties (*unknown*) have contracted with other parties (*unknown*) for a large quantity of aluminium, at prices varying between 10s. and 30s. per pound. It is needless to say that upon inquiry the contracting parties cannot be found. Aluminium, if placed upon the market at 20s. per pound, could undoubtedly be sold in large quantities, the demand rapidly increasing as the metal gained in favour, which, owing to its varied valuable properties, it would do to a certainty. It is allowed by all those familiar with the different items of cost in carrying out Deville's process, that, could sodium be obtained for 1s. per pound, aluminium could be made below a cost of 15s. per pound.

I think it is not, therefore, too much to claim for the "Castner process" of manufacturing sodium and potassium—now that it has been demonstrated commercially capable of producing sodium at 1s. per pound—that it is the greatest advance in the direction of producing aluminium at a cheap rate which has been made since Deville first demonstrated the possibility of producing that metal on a commercial scale.

It has long been known that the distillation of the metal sodium is rendered more easy by the use of a proportion of potash in the mixture. It is also known that a series of alloys of potassium and sodium can be produced, several of which are liquid, having much the same appearance as mercury when under naphtha. These alloys are very curious, one of them remaining liquid at 0° C., while another is lighter in its specific gravity than naphtha, upon which it floats. Specimens of several of these alloys are upon the table, and are open to your inspection.

◆

AN IMPROVED SYSTEM OF ELEVATING, SPECIALLY APPLICABLE TO ACIDS.

BY JAMES MACTEAR, F.C.S., F.I.C.

The problem of pumping or raising corrosive liquids is one which has given rise to various ingenious contrivances; but, in practice, these have been reduced to a system of raising with compressed air, in which the liquid to be raised is run into a reservoir, and then, by means of air, compressed to a sufficient degree, forced through a pipe to the height required, where it is delivered into a cistern, such an arrangement of delivery pipe being used as will prevent the splashing about of the liquid by the escaping air. It is unnecessary to describe this arrangement more in detail, it being so well known to all practical men. This apparatus is, however, unfortunately, not well suited for the elevation of hydrochloric acid, as the vessels and pipes must be constructed of a material to stand the action of this acid, which is by no means an easy thing to do. Pumps, constructed of such materials as glass, earthenware, guttapercha, ebonite, etc., and of various systems, have been tried; but these have never had much success, being expensive to erect and keep in order.

The apparatus which I purpose describing to you is one which is especially applicable to the raising of acids, and has been introduced by Messrs. Kuhlmann & Co. in France, where it has met with a large measure of success. It is called by them an "Emulseur," from the fact that in its action an emulsion of air, with the liquid to be raised, is formed.

If, for example, we take a syphon of this form and invert it, we find that liquid placed in the syphon will stand at the level of the shorter limb, any addition made to the level of the longer limb of the syphon will simply cause an overflow at the shorter limb: but if we lead a small tube into the longer limb, and allow a thin stream of air to bubble into the liquid, we shall find that the level of the liquid in the longer limb will rise to a very considerable height, the air of the liquid forming an emulsion, or intimate mixture of the liquid and bubbles of air, the mean density of which is considerably less than the liquid.

If we now allow a supply of liquid to flow continually into the short limb of the syphon, whilst at the same time we continue the injection of the air, there will be a continuous current of the liquid emulsion ascending the long limb, which may be drawn off at the highest level to which it attains by a proper arrangement. The new system of apparatus is based upon this principle, and is very simple, can be easily erected, and works with very little supervision, as once the apparatus is started it continues to work continuously until the supply of air and acid is suspended.

Let us take, for instance, the case of a Glover tower, which has to be supplied from a chamber erected in the usual way upon columns, say 20 feet from the ground. All that is required is that the supply pipe from the chamber should be brought down to or near the ground, then turned upwards, and be continued to the top of the Glover tower, so as to deliver into the cistern. A short distance above the bend at the ground level, the air pipe is introduced, and a small stream of air allowed to rise in the pipe. With the constant feed of acid and of air, the delivery at the top of the tower is constant, and requires no supervision whatever.

The drawing No. 1 shows this form of arrangement, and represents an apparatus capable of raising 800kilos. of sulphuric acid per hour to a height of 45 to 60 feet, the expenditure of air required being about equal to 5 litres of air per kilo.; the amount of air required is a little more than with an ordinary "montjus" or "acid egg," but the cost of repairs to the cocks, etc., of the latter apparatus far more than counterbalances the extra cost of air, whilst there is a very large saving in the cost of labour for attendance on the apparatus, no cocks having to be turned on and off, as is the case with the montjus.

In some cases, where compressed air is not available, the apparatus is worked by means of an exhauster such as the "Korting" steam jet, which is so well known. This form of apparatus is very easily and cheaply erected, and especially suitable where the liquid to be raised is to be taken at the ground level.

This arrangement is applied to the raising of muriatic acid. A vacuum is erected by a steam jet in the series of vessels, and the acid is thus sucked up to a certain level; a small air tap at the bottom being opened allows of the necessary quantity of air entering, the effect being to deliver a constant stream of the acid into a reservoir. So soon as this is full enough, which is shown by a glass indicator let into the pipes, the aspiration is stopped for the moment, and the liquid run out of the reservoir. The run-off tap of this vessel is again closed, and the aspiration again started, and so on. The results obtained with this apparatus are exceedingly satisfactory.

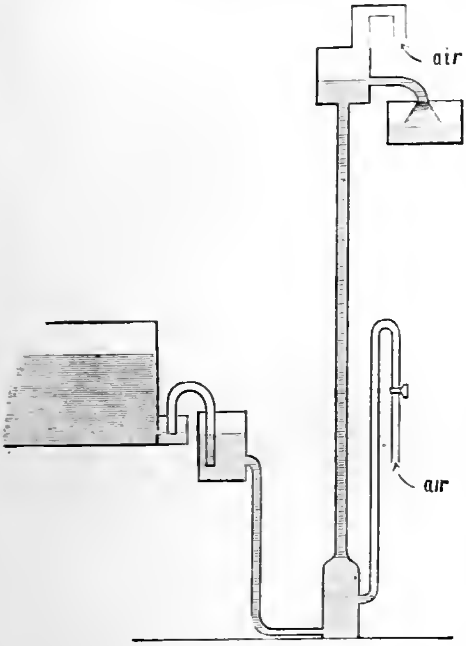

FIG. 1.

With acid of 32° Tw., an ordinary injector creating a vacuum, will only be able to raise it to the height of 18 or 19 feet, where it will oscillate; but, when the air-cock is opened to the proper extent, the emulsion formed can be raised to 35 to 40 feet. If the receiver contains, say, about 150 litres, it can be filled in from 7 to 10 minutes. The aspirator is then stopped and the receiver run off, when the apparatus is again turned on and the process continued. By a slightly more complicated arrangement, with two reservoirs or receivers, the process can be made practically continuous; but, with the one in question, which I have just described, from 600 to 800 litres per hour can be raised without difficulty.

Various slight modifications in the construction are made to suit special circumstances, but the general principle is the same in all cases.

The third form of this apparatus is applied to the ordinary montjus, and is applicable to cases where the pressure of the air is not sufficiently strong to elevate to the height required. In this case a pipe communicates between the air supply and the rising main in such a way that in addition to the pressure of the air upon the surface of the liquid in the montjus, a small proportion of the air is allowed to escape into the rising main, forming an emulsion reducing the density of the liquid, and enabling it to be carried up 2 or 3 times the height due to the actual pressure of the air itself.

ERRATUM.—In Mr. Wingham's paper (this Journal, February number, page 76), as regards the numbering of the woodcuts Figs. 1 and 2, read that numbering in reverse order.

Liverpool Section.

Chairman: Prof. J. Campbell Brown.

Vice-Chairman: Dr. F. Hurter.

Local Sec. and Treasurer: W. P. Thompson, 6, Lord Street Liverpool.

Meetings will be held at University College Laboratory, Brownlow Street, on April 6 (Annual Meeting) and May 4, and the following papers have been promised:—

Mr. C. Longuet Higgins, "On the Manufacture of Potassium Chlorate by means of Magnesia."

Mr. J. W. Macdonald, "On the Manufacture of Arrowroot in St. Vincent, West Indies; its Uses and Adulterants."

May 4.—Discussion on Mr. Westmoreland's paper "On the Estimation of Sulphur in Pyrites."

Notices of Papers and Communications for the Meetings to be sent to the Local Secretary.

A Meeting was held in the Chemical Theatre of the University College, Brownlow Street, on Wednesday evening, March 2, 1887.

PROFESSOR CAMPBELL BROWN IN THE CHAIR.

THE CHAIRMAN called attention to some specimens of quinones. These were formerly curiosities, but some of them are now used in the manufacture of dyes. Some are still curiosities; they are now, however, acquiring new applications.

Mr. W. P. THOMPSON (secretary), laid on the table a blasting plug. It consisted in a wedge or wedges, and a wooden plug with planes complementary to the wedge. In the wedge-shaped grooves thus formed at one or both ends the wedges were inserted and the whole placed in the blast hole; a little tamping was then thrown in and lightly tamped. The explosion drove the wedge or wedges into the block, splitting it, and wedging it tight in the hole. This apparatus was very cheap, and was found to give a better result than ordinary tamping, was safer, and saved time and labour. It was the invention of a Mr. Francis, mining engineer, and had been largely used with water cartridges and others.

The CHAIRMAN then called on Mr. Driffield to read his paper.

SUGGESTIONS ON BOILER MANAGEMENT.

BY VERO C. DRIFFIELD.

Steam may be regarded as the mainspring of chemical industry. There is hardly an operation connected with chemical manufacture which is not dependent upon steam. Anything, therefore, which relates to economy and safety in the use of steam must have an interest for the chemical manufacturer, and, with this in view, I have been prevailed upon to bring before you to-night a few practical suggestions which, I think, tend in the direction I have named.

I can hardly hope to lay before you anything very new or very original, but what I have to say is the outcome of practical experience with boilers for some years past. My remarks will, therefore, be essentially practical, and I shall have very little to say of theoretical considerations.

I do not propose to call your attention to any special design of boiler, nor am I going to enter into constructive details generally, but my remarks will apply to boilers which are already in use, and which I assume will, in the great majority of cases, be boilers of the ordinary Lancashire or Cornish type. My object is to point out certain parts of the boiler which I have found peculiarly liable to suffer from wear and tear, certain matters which tend to the waste of fuel, and others which render the boiler liable to become a source of danger. At the same time I hope to point out precautions and remedies which, in my own practice, I have found to prolong the life of the boiler, to save fuel, and to avert danger.

One of the greatest difficulties the steam user has to contend with is incrustation, or the deposition within the boiler of solid matter which has been dissolved or suspended in the feed water. This incrustation causes enormous loss of fuel by preventing transmission of heat to the water, and it is liable to lead to overheating of the boiler plates.

This solid matter contained in the feed water generally consists mainly of the carbonates of lime and magnesia, and of sulphate of lime. These carbonates of lime and magnesia are held in solution by an excess of carbonic acid, which is driven off when the water is heated, and these salts are then precipitated. They are, however, precipitated not as a hard incrustation, but in a light, powdery form, and they may, in themselves, be regarded as the least objectionable substances introduced into the boiler. The carbonates of lime and magnesia, however, become objectionable if three conditions are not fulfilled. These conditions are, first, that the flues are allowed to cool well down before the boiler is blown off, otherwise, when the water is removed, the heat from the flues will bake these precipitates into a hard scale which is difficult to deal with, whereas in the flowery state they admit of easy removal. Secondly, that tallow be not used for lubricating engine cylinders if the exhaust steam from the cylinders be used directly to heat the feed water, as tallow combines with the precipitated lime and magnesia, and forms with them a soapy mass which is more liable to lead to danger than is a hard but brittle scale. Thirdly, that any sulphate of lime there may be present in the feed water be decomposed, otherwise the hard incrustation, formed by the precipitation of this salt, will incorporate itself with the lime and magnesia, and so prevent the easy removal of the latter salts.

With respect to the magnesia, this salt is found in the scale and mud of the boiler, not as carbonate but as hydrate, as is shown by the analyses I have here, there being no carbonate of magnesia at all in the scale, and very little indeed in the mud. The magnesia is, however, precipitated, in the first instance, as carbonate, and is only converted into hydrate after prolonged exposure to the temperature within the boiler. This fact seems to have escaped the attention of Mr. Macadam, who read a paper on "Boiler Incrustations," which appeared in our Journal, vol. ii. page 12, and who throughout puts down his magnesia as carbonate. This hydrate of magnesia bakes into a hard scale much more readily than does the carbonate of lime if the flues are not well cooled down before the boiler is blown off.

The presence of sulphate of lime in the feed water is a much more serious matter than is that of the carbonates I have named, as sulphate of lime deposits itself, as is well known, in the form of a hard scale, which tenaciously adheres to the plates and is very difficult to remove. Another salt, which is also very objectionable in the feed water, is chloride of magnesium. This salt rapidly decomposes as the temperature of this water is raised, and sets free hydrochloric acid. I need hardly say what a source of mischief, and indeed danger to a boiler, the presence of free hydrochloric acid must be.

Quite recently my attention was called to serious internal corrosions which were taking place in a group of our boilers. For some time I attributed this to having fed the boilers partly with some hot distilled water which I thought it a pity to waste. Distilled water, we all know, has a highly corrosive action upon wrought iron. I discontinued the use of the distilled water, but the corrosive action still went on. I now had an analysis made of the water used for feeding the boilers, and found that it contained an abnormally large quantity of chlorine. Evidently something had gone wrong at the well, and this eventually proved to be the case; the well bottom had broken in, and we were pumping surface water which was clearly in communication with the river. The well was repaired and the trouble was at an end. When my attention was called to the water it contained 29·8 grains of chlorine to the gallon; but after the well was repaired the quantity rapidly declined to 2·2 grains, the normal amount. The water also contained considerably more magnesia than it formerly did, so that we may reasonably infer that the corrosions which were taking place in the boilers were due to hydrochloric acid arising from the decomposition of chloride of magnesium.

Now there are few things which have received more attention than have means to prevent or to render innocuous the presence of these substances in water used for feeding steam boilers. The patents taken out, and the nostrums of one sort or another proposed for this purpose, are simply legion. The great object of an anti-incrustator is to prevent, as far as possible, the precipitation, in the form of a hard scale, of the solid impurities contained in the feed-water and to neutralise any free acid which may be present, or which may be formed by the decomposition of the salts. Whatever substance will best accomplish this, without being otherwise injurious, is the best anti-incrustator to use. Of course, such a process as Dr. Clark's for purifying the feed-water before it enters the boiler at all, is, theoretically, the best to adopt; but it necessitates so much care and accuracy in carrying it out, and requires so much space for settlers and filters, that it is seldom adopted at all. The only plan open to us, therefore, is to deal with the solid impurities as best we may within the boiler itself. I shall show you presently, however, that the feed water may be purified to a considerable extent, before it reaches the boiler at all, in its passage through a feed-water heater.

So far as I can ascertain, nothing has ever been proposed which is practically better adapted for preventing incrustation than the introduction into the feed-water of carbonate of soda. Carbonate of soda has, of course, no influence upon the carbonates of lime and magnesia; but, as I have said, these salts are comparatively harmless in themselves, and easy to deal with. It is upon the sulphate of lime and the chloride of magnesium that the action of carbonate of soda is so beneficial. The action of carbonate of soda upon these salts is, of course, to decompose them, preventing, in the case of sulphate of lime, the formation of hard scale; and, in the case of chloride of magnesium, the production of free hydrochloric acid.

Now, as to the introduction of carbonate of soda into the boiler, the practice of some is to put it in in large quantities before the boiler is set to work again after being washed out. If this is done the soda is probably entirely removed by the blow-off cock long before the boiler comes to be washed out again; and, from the large quantity of soda put into the boiler to commence with, priming is very liable to ensue. I much prefer to inject the soda dissolved in the feed-water in regular daily amounts. When we consider presently the question of a feed-water heater, I will show you how I deal with the soda. The best salt of soda, I think, for the purpose is the carbonate; caustic soda is open to the objection that it has a serious action upon the brass fittings of the boiler. As to the best form of carbonate of soda to adopt as an anti-incrustator, I would recommend, as being more convenient for use, that which is most readily soluble, and which contains the greatest amount of alkali in a given weight. Of course, the freer it is from impurities the better. As to the quantity, this will, of course, vary with the salts dissolved in the water which have to be dealt with; but my own practice is to inject daily into the boiler an amount of alkali sufficient to decompose the sulphate of lime which analysis shows to be present in the feed-water. Of course if chloride of magnesium is present, there must be, in addition, sufficient alkali to decompose this salt also.

I must ask you to refer for a moment to the table of analyses before you. The feed-water, of which this table gives the analysis, is yielded from a well on the works, and is that with which most of our boilers are fed. It contains, as you see, 37·40 grains of solid matter in the gallon. Of this, 19·68 grains, or the bulk, is carbonate of lime. Fortunately there are only 2·14 grains of sulphate of lime, which is a very moderate quantity, and no chloride of magnesium at all. We have, therefore, only to deal with the sulphate of lime, and it is easy to calculate what quantity of carbonate of soda this sulphate of lime will require to decompose it. Supposing a boiler evaporates 35 cubic feet of water an hour, this would mean a deposit in the boiler, in 24 hours, of 1·6lb. of sulphate of lime, and this requires for its decomposition 1·25lb. of pure carbonate of soda. We have, therefore, only to inject into the boiler an amount of carbonate of soda sufficient to decompose any sulphate of lime and chloride of magnesium there may be present; and if, on a strip of neutral litmus paper, the water in the boiler has a distinctly alkaline reaction, we may be sure that we are doing all that can be done chemically. The water for testing may conveniently be taken from one of the water gauges.

With respect to the analysis of the hard scale which was taken from a boiler fed with this water, the first point which strikes one is the satisfactory way in which the addition of carbonate of soda to the feed-water has done its work. You see it has almost entirely decomposed the sulphate of lime, there being only 0·51 per cent. of this substance present in a scale which has probably been many months in the course of formation. This analysis shows that the chief constituent of the scale is hydrate of magnesia, and the only way to check the conversion of this substance into a hard scale is, as I pointed out before, to prevent its being baked upon the plates after the water is blown out of the boiler. The analysis of the boiler mud shows that a considerable amount of hydrate of magnesia exists in a powdery form.

To render the analysis of the scale more complete and valuable I append separately the acids and the basis comprising it:—

CO_2	17·48
SiO_2	10·70
SO_3	0·30
Cl	0·07
MgO	31·01
CaO	22·25
Na_2O	1·75
Fe_2O_3 and Al_2O_3	1·21
Water	11·99
	99·70

As to accessory measures for preventing incrustation, I would further impress the importance of allowing the boiler to stand for as long as possible after the fires are drawn before it is blown off. It is perfectly obvious that if the boiler is blown empty while the flues are still hot, the plates will become hotter than they were before, and, ignoring any injurious straining of the boiler itself, the precipitated lime and magnesia will bake hard. If, on the other hand, the flues are allowed to cool well down before the boiler is blown off, the powdery condition of these precipitates will not be interfered with, and they can then be easily removed. In the next place it is a good plan to blow about an inch of water out of the boiler at least twice a day; this removes a considerable amount of the precipitated salts, and, at the same time, insures the blow-off tap being kept in working order. If this tap is never used, excepting when the boiler is entirely blown empty, it will then very probably be found to be blocked with scale, and cannot be used at all. This leads to pricking the tap, or loosening the plug, which are dangerous operations, and renders blowing-off in an emergency often out of the question. Then, as to washing out, I think it is a doubtful economy to allow a boiler to work too long before it is thoroughly cleaned. My own practice is to wash a boiler out every four weeks, which, for one working day and night, is seldom enough. This, however, largely depends upon the nature of the feed-water used. It is also desirable to adopt a form of feed-water heater which will, as far as possible, collect within itself the solid impurities of the water, so that a great proportion of them never reach the boiler at all. Of this I shall have more to say when speaking presently of water heaters.

In spite of these precautions, the formation of hard incrustation will sometimes gain ground, when it will well repay to resort to scaling, which should, of course, be carefully done, so as to prevent injury to the boiler plates. I have upwards of forty boilers in my charge, but it is very rarely indeed that I have any occasion to resort to scaling. I have seen it stated that an incrustation $\frac{1}{16}$th of an inch in thickness is equivalent to a loss in fuel of 20 per cent., and that the loss in fuel increases very much more rapidly than does a proportionate increase in the thickness of the scale. In addition to those disadvantages to which I have already called your attention, I must add the fact that the presence of incrustation in a boiler always renders inspection difficult and generally unsatisfactory.

water. By allowing the steam, however, to mix directly with the water, almost the entire heat is absorbed, and the heater necessary for the purpose is a much simpler and less costly apparatus than when the steam is caused to circulate through pipes. The only point to be attended to in using open steam is that tallow must not be used for lubricating the engine cylinders, as, if tallow finds its way into the boilers, it becomes, as I said before, a source of mischief and danger. This it does by combining with the precipitated carbonates, and forming with them a soapy yielding coating on the flues, exceedingly likely to lead to overheating of the plates, and also by decomposing and producing fatty acids which are highly injurious to the boiler. Tallow may, however, be very advantageously substituted by one of the many mineral lubricants now to be had, for not only are these lubricants harmless in the boiler, but, unlike tallow, do not injure the cylinders. It is only by using these mineral lubricants that the insurance companies are at all likely to tolerate the form of heater which I am advocating.

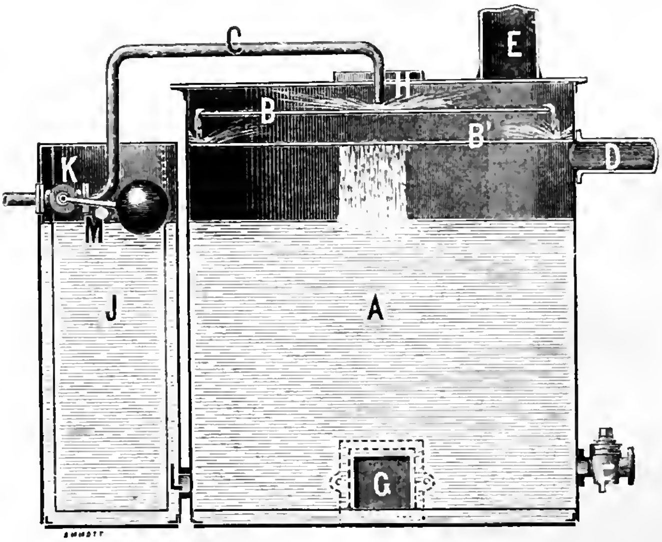

FIG. 1.

I will now ask your attention to drawing No. 1. This drawing represents a form of feed-water heater which I have had in satisfactory use for many years past.

From most chemical works a large amount of waste heat passes away in the form of exhaust steam, and this heater is designed to utilise this exhaust steam. In a chemical works, unlike a cotton mill, the power is generally supplied from a number of small engines scattered over a large area, and the boilers are, instead of being placed in one continuous range, divided into a number of groups. The plan I advocate is to provide a heater for each group of boilers, and then to apportion to each heater a share of the exhausts which lie nearest to it.

There are two forms of heaters adapted to utilise waste steam—that in which the steam is caused to circulate through pipes placed in the water to be heated, and that in which the steam is allowed to enter directly into contact with the water itself. Now the objection to heating water with closed steam is that the heat from the steam has first to pass through the pipes before it can get to the water, and the pipes very soon become so thickly coated with scale as to almost entirely prevent transmission of heat to the water.

A represents a cylindrical vessel which may be conveniently and economically made of a portion of an old boiler shell. At the top of this vessel are two circular shelves B and B^1. B, the upper shelf, is not quite so large in diameter as the vessel itself, and so allows an annular space between its edge and the inside of the vessel. B^1, the lower shelf, fits closely at its edge to the tank, but is provided with a circular hole in the centre. C represents the pipe through which the cold water is supplied to the heater. This pipe is reduced in area at the extremity which enters the heater, so that the water is injected at a considerable pressure. The water impinging against the upper plate B is broken up into a fine spray, more or less filling the space above the shelf. The water finds its way through the annular space down on to the under plate B^1, and from thence through the circular hole into the body of the heater. The exhaust steam enters through the pipe D, and is compelled to take the same course as the water, though in the contrary direction, before it can find its way out at the chimney E. As many exhausts as the capacity of the heater will admit may, of course, be placed round the vessel on the same horizontal line as the one shown. By the time the steam has passed through this apparatus it is almost, if not entirely, condensed, and the amount emitted by the chimney is very small indeed

The hot water is drawn off at the tap F, which may with advantage be fixed higher up the side of the vessel than it is shown in the drawing, in order to allow more room for the settlement of the precipitated salts. G is a manhole, which is used for cleaning out the heater, an operation which it is desirable to carry out once a week, for one great advantage of this heater is that a large amount of the solid matter contained in the feed-water is precipitated within it, and so prevented from ever reaching the boiler at all. On the bottom of the heater I always find a plentiful deposit in the form of mud.

In order to show you what an amount of service these heaters render in purifying the feed-water before it enters the boiler, I may tell you that an analysis of the water on leaving the heater showed that it contained only 17·5 grains of solid matter to the gallon, while the water supplied to the heater itself contained, as we have seen, 37·4 grains. You see, therefore, that the heater has deprived the water of more than half the solid matter which it originally contained. The solid matter retained by the heater is chiefly carbonate of lime, as you will see from the analysis of the mud taken from the heater that it only contains 5·3 parts of magnesia for every 100 parts of lime, while the feed-water originally contained 16·8 parts of magnesia for 100 of lime.

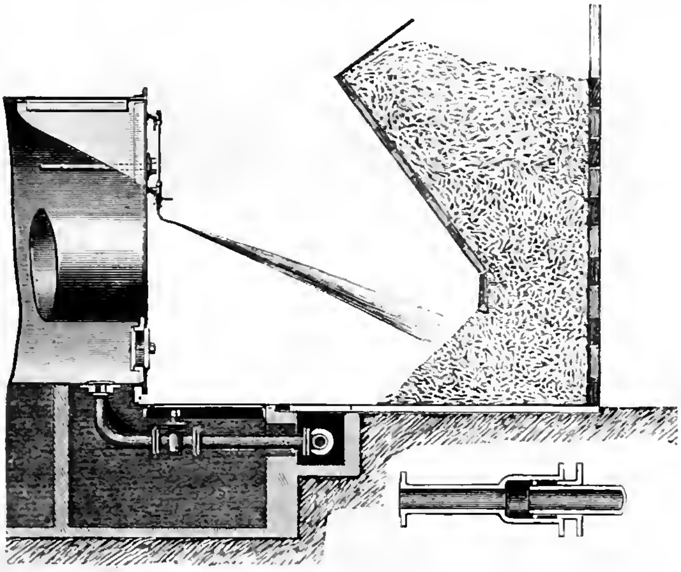

FIG. 2.

On the top of the vessel, where the water pipe enters, is a circular hole H, which is covered with two semi-circular plates, which are easily removable. It is through this hole that the daily quantity of soda is introduced, when it is, of course, soon washed down into the body of the heater, and from thence finds its way into the boilers. The object of the tank J at the side is simply to maintain a constant water level in the heater, and to render the whole apparatus automatic. This is attained by means of the ball valve K, which would not, of course, work in the heater itself, because, in the first place, of the agitation of the water, and secondly, because the balls of these valves working in hot water soon become coated with incrustation, when they lose their buoyancy, and are so rendered useless. The water in the tank J, which communicates with the heater by the branch L, is, of course, comparatively cool and quiescent. The hole M is simply an overflow, which comes into play if the ball valve should stick, or fail from any cause. A pipe from this overflow may advantageously be conducted to the vicinity of the firemen, so as to call their attention should anything go wrong.

Apart altogether from the saving effected by heating the water with waste heat, whether derived from the flues or from exhaust steam, it must not be forgotten that it has an important tendency to prolong the life of the boiler itself. A boiler which is fed with cold water is subjected to irregular straining, which will inevitably render it more liable to leakage and ultimately to injury.

In my experience, that part of a boiler which is most liable to suffer from wear and tear is the bottom of the front end plate, and the bottom of the first plate of the shell, together with the angle-iron which connects these plates. There is so much damp about here, arising from the difficulty of keeping the connection between the boiler and the blow-off pipes perfectly tight; from dripping and discharge from the water gauges; and from slaking cinders upon the foot-plate; that, without great attention, corrosion is sure to set in sooner or later.

If you will refer to drawing No. 2, I will advise the adoption of several precautions which, if carried out, will do a great deal to preserve this part of the boiler from injury. First of all, have a good, substantial cast-iron foot-plate, consisting of a frame with a large plate let into it, which plate can be taken up so as to give access to the hearth-pit. In the large plate let there be a hole just over the blow-off tap, which hole is also fitted with a plate, making the entire surface of the foot-plate uniform, and have it chequered. Let this foot-plate be fixed fully 3 inches below the level of the front end angle-iron, so that any damp cinders which may lodge beneath the angle-iron are easily removable. Avoid wrought-iron foot-plates; they warp, and allow cinders to get down, and injure the blow-off pipes and taps, and the firemen are liable to slip upon them. Just behind the angle-iron have a cast-iron feeder in two pieces, put in one from either side, and resting upon the foot-plate. Let the brickwork, too, at the front end of the boiler be kept well behind the angle-iron, so that any leakage from the front joint may be easily discovered and checked. Insist upon the hot cinders and clinkers being brought forward from contact with the boiler front before they are slaked, and do not allow the water to be thrown upon the front of the boiler. Better still, have the hot cinders and clinkers removed in iron barrows and slaked elsewhere, but in either case let them be removed as soon as possible, otherwise, apart from the probability of their injuring the boiler, firing will be carried on over them, and fuel will fall among them and be wasted.

With respect to leakage from the joint connecting the boiler to the blow-off pipes, the best way of preventing this is to take care that there is plenty of freedom and elasticity in the blow-off pipes themselves. Do not allow the pipes to be buried in the ground, but let them lie in a channel, as shown on the drawing, supported on bars of iron built in. Let the channel be simply covered over with the flooring flags, so as to be easily accessible. Where there is a range of boilers, put, at intervals, into the line of blow-off pipes connecting them an expansion joint. These expansion joints may be quite cheaply constructed, as shown on the drawing, and I find they are sufficiently good for this purpose, without going to the expense of boring and turning at all. If these pipes are treated as I suggest, and are perfectly free to move under the influence of varying temperature, the difficulty of keeping the joint beneath the boiler tight will disappear. If the pipes are fast in the ground, on the other hand, this joint will be a continual source of trouble, and the pipes themselves will give way at their joints, if they do not, at times, actually break.

I consider the blow-off joint the most important one about a boiler, as, apart from the injury it will cause if it leaks, should the joint-ring blow out altogether, it is very probably almost impossible to get at the fires to draw them; and so serious injury may be caused to the internal flues, and the fireman will possibly be scalded.

Every six months, or whenever the boiler flues are cleaned, I would advise that the under-side of the first shell-plate of the boiler and the front-end angle-iron be well painted with red oxide paint the whole width of the bottom flue, extending inwards up to the cross wall. This assists wonderfully in preserving this part of the boiler from injury by damp.

As to the blow-off tap itself, the first desideratum is that it should be tight. This is best secured by adopting a good asbestos-packed tap, and then taking care that the plug is not removed when the boiler is washed out. If the plug is removed, small particles of scale are liable to get between it and the shell, when the tap will soon become leaky. If the tap is opened twice a-day, as I suggested, it will not be at all liable to choke up with deposit, and will therefore afford no excuse for removing the plug. A blow-off tap should also be one of the straight-way type; the passage through it should be in a straight line, and not angular.

With respect to the water gauges, it is a mistake to adopt cheap and lightly constructed ones. They should also be tight, otherwise they will drip on the foot-plate and keep the front end of the boiler damp. The next point is that they should have ample sized passages through them, otherwise they are liable to choke up and mislead. There should never be less than two sets of water gauges on one boiler. Many steam users bring the waste pipes from these gauges down on to the foot-plates, just where we have already seen dampness is particularly objectionable; others discharge the water from these gauges into the internal flues, which is also to be deprecated; others, again, discharge into a drain for the purpose. But, in any case, these plans necessitate pipes of small bore to carry away the water from the gauge taps, and these pipes are constantly stopping up with deposit, and are always a source of trouble. The plan I have found best is to attach to the bottom gauge taps a few inches of small iron gas-piping, bent so as to direct the water on to the slack in front of the boilers. This prevents the water doing any mischief to the boiler front, is cleanly, and gives no trouble from the pipes stopping up. If the taps are tight, which good asbestos-packed taps will be, nothing beyond these short bent pieces of piping are requisite; but if the gauge taps leak at all, they will probably require supplementing with ordinary gas taps screwed on to the ends of the bent pipes.

If the points to which I have directed your notice are properly attended to, you ought to secure almost entire immunity from the deleterious action of damp and cinders upon this most vulnerable part of the boiler, and upon the blow-off pipes beneath.

There is one other part of the boiler which is peculiarly liable to suffer from wear and tear. I refer to grooving, which is liable to arise in the two end plates immediately around the angle irons which connect them to the internal flues. This mischief is, in the first instance, due to mechanical forces produced by the expansion and contraction of the boiler under the influence of varying temperature, and is induced by too great rigidity and want of elasticity. If this grooving is found to be taking place, examine the gusset-stays at once, and if they are fastened to the end plates nearer than nine inches from the angle irons of the flues, release them by removing the bottom rivets until this distance can be secured. Look, also, to the horizontal stays; these should not be too taut, but should be capable of vibrating three inches when smartly pulled in the centre. Any stays there may be in the boiler for supporting these rods are better removed.

Before we leave this drawing, I should like to call your attention to one or two other points. With respect to the mud-hole in the boiler front, it is customary to make the joint with an indiarubber ring twelve or thirteen inches in diameter. These rings are expensive, and if no precaution is taken the ring will be torn when the joint is broken, and a new one will be required every time the boiler is washed out. If, however, the side of the ring which comes into contact with the mounting on the boiler be painted with a mixture of blacklead and tallow, the ring will adhere to the mud-hole cover, but will readily leave the mounting; and it may, by this simple attention, be used over and over again.

On the other side of the drawing you see a bin for the purpose of holding the slack. This is an arrangement I most strongly recommend as having great advantages over the rough and ready method of discharging the fuel on to the floor of the boiler-house. In the first place, this bin saves fuel, as it keeps it from under foot, and prevents its admixture with the cinders and clinkers. The bin also saves room, as it is obvious that the fronts of the boilers may be placed nearer the outside of the building than if room has to be left on the floor for the slack. In the next place the bin prevents slack-dust from entering the building, a nuisance which is particularly great if the boilers are in proximity to any chemical produce which it is an object to keep white. Lastly, this bin equalises the quality of the fuel. If the slack is discharged on to the floor of the house, it will be found that the fine stuff will always accumulate at the back, while the good rough slack will roll down to the front and be used up first, leaving the fine to be dealt with alone afterwards. With this bin, however, a fair admixture of the coarse and the fine slack is secured throughout.

There are two directions in which the hot gases may be caused to travel through the flues of a boiler. In both cases they, of course, first of all pass through the internal flues; but after this the difference arises. One plan is to cause them to pass next through the side flues, and lastly under the bottom of the boiler. The other plan is the reverse of this, and after passing through the internal flues the hot gases are caused to pass under the bottom of the boiler, and lastly through the side flues. The latter is, I think, the better plan, for the following reasons:—First, the coolest water is at the bottom of the boiler, and as it is a great object (in order to prevent straining of the boiler) to preserve an equable temperature within it, I prefer to apply the hottest gases to the coldest part. Secondly, the value of horizontal heating surface is very much greater than that of vertical; therefore, by applying the hottest gases to the underside of the boiler, the heat is more thoroughly absorbed than it would be by the vertical plates in the side flues. Now, a main reason why the course I advocate is often not adopted, is in consequence of the difficulty of making the flue divisions at the back end of the boiler sufficiently tight to prevent the hot gases escaping to the chimney without passing through the external flues at all. The setting at the back end is decidedly more easily made tight if the plan I deprecate is adopted.

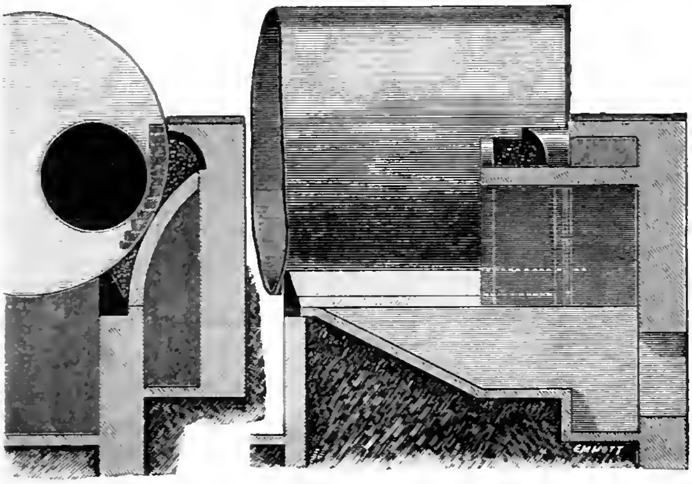

Fig. 3.

I think I can show you, however, that the plan I advocate for the course of the hot gases is quite compatible with tightness, and I shall ask you to refer to drawing No. 3. Please remember that, after the gases have left the internal flues, we want them to pass along the bottom flue back to the front end, then through the side flues, and out to the chimney. At the back end of the boiler it is therefore necessary to build partitions to prevent the gases passing to the chimney before they have traversed the bottom and side flues. These partitions usually consist of stepped brick midfeathers built into the back end wall, and brought up against the back end of the boiler, as indicated on the drawing. Now, these midfeathers are excessively unstable things, and time after time, when examining boilers, I have found them to have more or less given way, and the hot gases to be escaping straight to the chimney, without doing any work in the bottom and side flues at all. Apart from the instability of these walls, it is difficult to keep them so closely in contact with the boiler end as to prevent, in any case, some leakage, on account of the expansion and contraction of the boiler itself. Anxious to retain this particular course for the circulation of the gases, and at the same time anxious to avoid these losses, I adopted the plan of making good the flues at the back end of the boiler which is shown on the drawing.

Instead of building a stepped wall against the end of the boiler, I build an arch into the end and side walls, and allow it to enter about two feet into the side flue, just clearing the boiler. The space between the boiler and the arch is filled with dry sand, which is prevented from running out at the sides by pieces of brick shaped to fit. The boiler is now free to move over these arches without producing any crevices which can lead to leakage and loss, and the arches themselves are thoroughly stable structures. I have found this plan a complete preventive of loss, as it compels the hot gases to traverse the entire length of the flues, and at the same time to take that course which I believe to be most desirable.

While speaking of flues, I should like to impress upon you the desirability of making the side flues more roomy than they are frequently constructed. If every designer of a boiler setting were made to crawl up a hot side flue, he would agree with what I say. Some people think that six inches wide in the narrowest place is sufficient, but in the interest of efficient examination, and of the inspectors themselves, I would say never make this width less than nine inches.

When one boiler in a range is laid off, it is found that, unless the gland of the junction valve be well and freshly packed, the water which condenses in the steam main connected with the idle boiler, will be forced out through the gland of the valve, by the steam pressure in the other boilers. This water is a great nuisance on the top of the boiler, but, what is worse, it finds its way into the flues, and keeps the covering tiles and the seating blocks damp, and very probably gives rise to corrosion. Now, of course, this may be met by having a separate drainpipe attached to the lowest point of each rising main, and slightly opening a tap on the outlet end every time a boiler is laid off. Taps, however, are liable to leak when they are not wanted to, and this arrangement also requires attention in opening and closing the tap at the right time.

Drawing No. 4, however, shows you how the difficulty may be overcome perfectly automatically. The drawing shows two junction valves fixed upon boilers: the right-hand boiler is supposed to be working, and the left-hand idle. Above is the steam main to which the rising mains from the junction valves are connected. The right-hand junction valve is open, allowing the passage of steam from the boiler, and the left-hand valve is closed. The rising main from the closed junction valve will, of course, gradually collect condensed water, which, if nothing is done to prevent it, will be forced through the gland of the valve, but if the rising main of the idle boiler be connected with the rising main of one which is working, by means of an inch pipe, as shown, the water which collects will be forced back into the working boiler through its open junction valve. This takes place because the pressure of the steam, and the slight plus pressure due to the head of the water itself on the one side, will overcome the steam pressure alone on the other.

The junction valves are purposely not shown on this drawing in the positions they usually occupy, in order to indicate the arrangement more clearly. On this drawing only two boilers are shown connected, but if there are a number of boilers in the range, the drain pipes may, with advantage, be continuous, and connect them all. You will observe that the drain-pipe is bent in plan between every two boilers; this is done to allow for expansion and contraction. The pipe should be constructed of copper, because of the action of condensed water upon wrought iron. I adopted this arrangement with considerable misgiving, as I feared that the pipes would be liable to stop up with deposit carried over by the steam, but this is not the case, and the system works admirably.

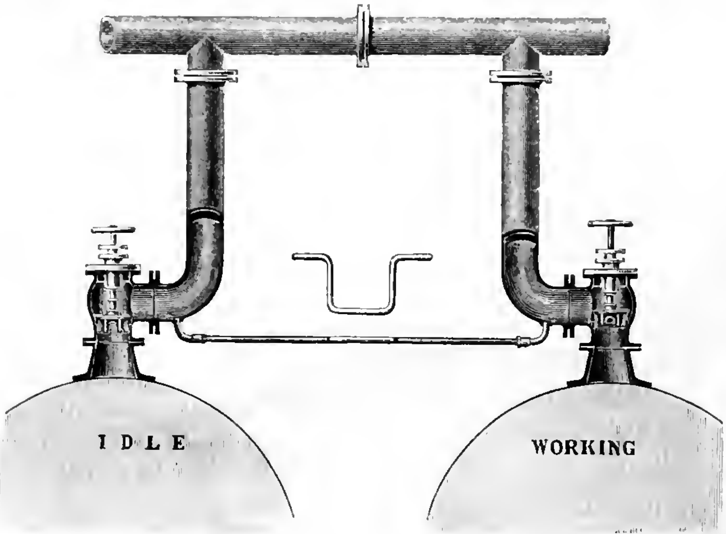

Fig. 4.

I have often been asked whether I consider the introduction of cross-tubes into the main flues of a boiler, an advantage. I am myself opposed to their adoption in all ordinary cases. At first sight it would appear as if cross-tubes must increase the heating surface, and consequently be beneficial; but it must not be forgotten that while the tubes do present more surface, it is *vertical* surface, and it is only obtained at the sacrifice of the horizontal surface which lies immediately behind them. For the tubes, as it were, cast a shadow, and deflect the hot gases from the upper part of the main flue, just where they would otherwise be most efficient. I have not made any actual experiments to support my opinion, but so far as I can judge, from general observation, I feel no doubt about the matter.

These cross-tubes render inspection much more painful and difficult, as anyone who has ever threaded his body through the maze of cross-tubes in a "Galloway" boiler will quite understand. These tubes, again, act as dust catchers, and a flue containing them will much sooner become choked with flue dust than will a flue which has no cross-tubes in it. It is obviously desirable to prevent the accumulation of soot and dust in the flues as far as possible. The only advantages which I think can be claimed for cross-tubes are that they strengthen the flues, and tend to promote circulation. If, however, the flues are constructed with the "Adamson" or "Bowling" seam, I don't think anything further is requisite to strengthen them, and if the boiler is fed with hot water, and the hot gases are caused to circulate as I have recommended, I don't think anything is needed to improve the circulation. In the rare cases of boilers fired with waste heat, when the heat passes through the internal flues only, these cross-tubes do certainly act beneficially in promoting circulation.

I shall probably be expected to say something regarding safety valves and fusible plugs. They are most important details of the boiler, and I believe that proper attention to them will do more to remove any liability to danger than anything else. There should always be two safety valves on each boiler, one of the ordinary deadweight type, and the other constructed to blow off when the steam pressure becomes excessive, or when the water level falls too low. To insure these valves never sticking, it is a good thing to have them lifted or moved upon their faces regularly once a week. Lever or spring safety valves, or any that admit of being tampered with, are dangerous, but it is seldom an object to a fireman in a chemical works to maintain an excessive pressure—the difficulty is generally to get the desired pressure kept up. Regarding fusible plugs, I would only say that to be efficient they must be kept clean, and they should be thoroughly cleaned on both sides every time a boiler is laid off. Every year the plug should be discarded and replaced with a new one whether it shows signs of leakage or not.

With respect to the supervision of boilers in a chemical works, I think the best plan is to appoint as foremen two steady and tried men, one for the day, and the other for the night shift. Of course this implies that there are sufficient boilers to warrant such an arrangement. These foremen should thoroughly understand the details of a boiler, and may with advantage be selected from among the fitters. It may then be part of their duty, when at work during the night, to attend to any minor fitting requirements that may be needed in the works generally. This will often save calling in the assistance of the regular fitters. These foremen may also be made the heads of any fire brigade organisation, because, as a matter of course, either one or the other, or, at any rate, a competent substitute, is always on the spot, and as their work necessitates their constant patrol, more or less, of the whole works, they become in fact general watchmen. The regular duty of the foremen is to see that steam is kept up, that firing is properly carried out, and that the evolution of black smoke is, as far as possible, prevented; to examine the boilers, and to see that any necessary repairs are executed. They see also that routine work, such as putting the soda into the heaters, is regularly attended to. Where the number of boilers is large, it is well to employ a fitter, whose duty it is to prepare the boilers for work again after being washed out, or before and after flue cleaning. This duty may, however, devolve upon the foremen, if the number of boilers does not warrant the employment of a fitter in addition, but there are so many little repairs needed in connection with the boilers and the pumps, that any spare time a fitter may have, may be usefully filled up.

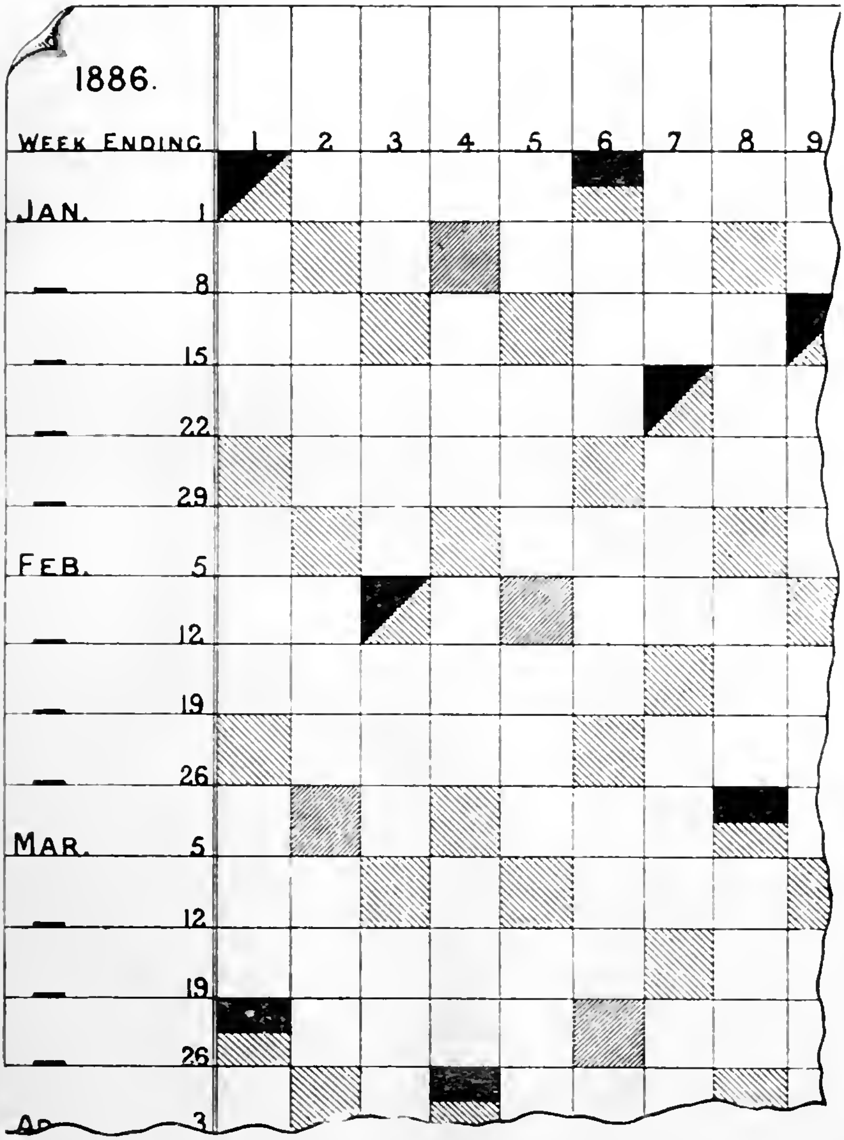

FIG. 5.

I find it an excellent plan to pay the foremen a small annual bonus upon each boiler, the amount being based upon the nature of the report received from the insurance company. This is a decided stimulus to their watchfulness and care, and goes a long way to prevent laxity in the execution of routine duties. It is always a difficult matter to secure regular attention to details which are of a routine character, and anything which tends to prevent rules falling into abeyance is an advantage.

A daily boiler report book should be kept by the foremen, and it should be their first duty on coming in to work to inspect the boilers and take their report. There is, therefore, a record taken every 12 hours, showing which boilers are working or idle, and the height of the water and the pressure of steam in each boiler individually. Remarks are also made in case any of the fittings are discovered to be inefficient, and in the book is entered when the boilers are washed out, the flues cleaned, and repairs executed, and by whom the boiler was examined. Each report is signed by the foreman making it; and, in case of any subsequent inquiry, records how matters stood when it was made. This book should be daily submitted to the head of the department to whom the foremen are answerable, and in whose hands the ultimate responsibility rests.

In addition to this record kept by the foremen, I find it necessary to keep myself two other books. In one of these I enter abstracts of the insurance company's reports, showing at a glance their remarks respecting the condition of the boilers, and their recommendations, if any, regarding them. This book is always consulted when the next opportunity arises for putting such recommendations into practice. The second book I keep is merely a record showing when the boilers are washed out, when the flues are cleaned, and when the annual inspection takes place. This ensures these operations being carried out at their proper time, and in their proper order. In order to show you how I record these matters so as most graphically to strike the eye, I refer you to diagram No. 5. This represents the corner of a page of this book, and gives you the record of eight boilers for a period of thirteen weeks. The blue squares indicate that the boiler has simply been washed out; the squares with the horizontal black band that it has been washed out, and that the internal flues have been cleaned; and the squares divided diagonally indicate that, in addition to washing out, the whole of the flues, both internal and external, have been thoroughly cleaned; the red squares indicate the same as the last-named, excepting that, in this case, the boiler has been thoroughly examined by the insurance company's inspector. You will observe from this diagram that it is my practice to wash a boiler out every four weeks; every three months the internal flues are cleaned, and every six months the whole of the flues are swept out. The inspection, of course, takes place upon one of the latter occasions. I find this method of recording these operations very satisfactory, as it is so easy to see at a glance when washing out, etc., becomes due. This book is of such a size that one opening represents a year's working. Every week end this record is consulted, and a list is made of those boilers which require attention in the ensuing week.

I have referred several times to boiler insurance companies, and I think I may say here that I consider them invaluable and indispensable agencies in successful boiler management. This is especially the case in works where there are comparatively few boilers, and where, consequently, the organisation is perhaps not as perfect as it might be. But, in any case, if the boilers are placed in the hands of a competent insurance company, it secures, at any rate, one thorough examination of each boiler in the year. No casual examination can ever be as satisfactory as one undertaken by a thoroughly trained inspector, who daily makes investigations of boilers, and who will often be led to suspect mischief from trifling indications, which would altogether escape the notice of one less experienced. Of course, I assume that the company selected is one which will do its work honourably, and will have the steam users' interests at heart. Fortunately, the steam users' interests are in reality identical with those of the shareholder—namely, to conduce to safety in the working of boilers.

We have now reached the end of those suggestions on boiler management which I intended to lay before you to-night. My paper has by no means exhausted the subject, and it has covered ground which is no doubt familiar to most of you; but I shall be very glad if, out of what I have said, you are able to glean a suggestion or two which may prove of any practical value. If the subjects I have spoken upon are familiar in themselves, their importance is, I believe, often insufficiently appreciated. I hope, however, that in matters of detail some novelty of treatment may be found. As far as I know, for example, the feed-water heater to which I called your attention is unlike anything of the kind in general use, and, on the other hand, my remarks on incrustation certainly contain nothing new. I have only tried to lay this subject before you in as concise a form as possible; and I wish here to acknowledge my indebtedness to my friend, Dr. Hurter, for the valuable assistance he has, from time to time, rendered, by making for me analyses, some of which I have placed before you to-night. Any value my remarks on incrustation may have is largely due to the interest he has taken in this subject. I also wish to express my thanks to Messrs. Gaskell, Deacon & Co., for kindly permitting me to place at the disposal of this Society the outcome of experience I have gained in the supervision of their boilers. I have called your attention to some points which are of a very trifling nature, but I believe that the constant exercise of watchfulness and care in matters of detail, trifling in themselves, will, after all, be found among the best suggestions on boiler management.

DISCUSSION.

Dr. J. **Campbell Brown** (Chairman) said that the large attendance showed the interest which had been taken by the members in the subject, which was more or less important to every manufacturer. He thought the way in which it had been treated, and the valuable suggestions which had been made, ought to call forth a good discussion. Besides the more chemical points, he was particularly struck by the reference made to cross tubes in boiler flues, and he hoped that some of the members would be able to give the results of practical experience with cross tubes. As Mr. Driffield said that he had not put his theories into practical test, perhaps it would not be too much to suggest that it would be of great advantage, not only to the members of the Society, but to the manufacturing community, if practical experiments were made to support or contradict the *a priori* theory which he (Mr. Driffield) had put before them. *Prima facie*, there was undoubtedly a great deal to be said for it.

Mr. **Gibson** said he would like to ask Mr. Driffield two or three questions. 1. Did he get his boilers absolutely clean? 2. Did he get them absolutely without corrosion? and, 3. What was the price of carbonate of soda? He was not in the chemical trade, but was exceedingly interested in the subject, and would like to have Mr. Driffield's replies.

Mr. **Brunner** said he wished to ask Mr. Driffield, and perhaps Dr. Hurter, for some further explanation with regard to the analysis. He noticed, for instance, in the analysis given of the boiler mud there was 3·1 carbonate of soda, and in the boiler scale 3·01 carbonate of soda. He would ask whether that did not point to the probability of an unnecessarily large quantity of carbonate of soda being used in the precipitation of impurities. He thought perhaps it was due to the formation of the insoluble compound of carbonate of soda and carbonate of lime, with which they were acquainted. With regard to the boiler scale analysis he noticed hydrate magnesia 44·9 and silica 10·7. Were they to understand that the magnesia existed there as hydrate, and the silica as free silica? It seemed to him, under the circumstances in which they existed in the boiler, very probable that the silica and magnesia would combine, and that that possible combination may have had a good deal to do with the formation of scale. It was rather a peculiarity that the boiler mud contained no silica. He would also like to ask Mr. Driffield a practical question, whether, if worked with as much care as Mr. Driffield evidently bestowed on the boilers under his charge, he could give any idea what the increased life of a boiler would be, compared with a boiler working under ordinary, somewhat careless, conditions as to attention? Also with regard to the amount of fuel consumed, how many pounds of water did he evaporate per pound of fuel in his carefully managed boilers, and what would be the amount of water evaporated in boilers which were not so well attended to? It seemed to him that those were points upon which every steam user would like to be informed, as upon these points depended whether or not it was advisable and whether it paid to spend a considerable amount of money in carefully attending to boiler management. He had no doubt himself that it did pay.

Mr. Wm. Ingham (Assistant Engineer, National Boiler Insurance Co.) said he would like to make a few observations on the very excellent paper. Mr. Driffield had admirably expressed the views held by most engineers, but there were certain points upon which they had little or no information. With regard to cross tubes, he had known many experiments made in which the cross tubes proved of no advantage. They advised cross tubes principally in cases where the flues were only strengthened by hoops, and in order to promote circulation. Many boilers were only fed by cold water, but the products of combustion were carried up the sides before passing under the bottom, and in such cases they generally found the ring seating of the shell to leak, whereas when the cross tubes were used they promoted the circulation, and there was not the same difference in temperature between the lower and the upper parts of the boiler. That and the additional strength given to the flues were the only advantages of cross tubes. With regard to prevention of incrustation, for a number of years most of the boiler engineers had recommended the use of soda ash; that was perhaps the most economical form of using carbonate of soda. He thought Mr. Driffield was not quite correct in his views about caustic soda. They had found that caustic soda had caused leakage in the brass fittings. Caustic soda was very efficacious with some kinds of water, and had a distinct advantage over the caustic lime used in Clark's process. The caustic lime threw down the carbonate. The caustic soda, however, absorbed the carbonic acid and formed carbonate of soda, which was available for decomposing any sulphate of lime present, converting it into carbonate of lime, and afterwards precipitating it. He thought, also, that Mr. Driffield was scarcely right in his view about the use of grease and tallow. It was not these that formed a scale, but rather they so thickened the water as to make a sort of accumulation, and this thickening of the water prevented a sufficient transmission of heat from the plates to the water. With reference to the waste of heating power through scale, it was a fact that probably nine-tenths of the evaporation was done in the furnace, and very little was done in the bottom parts of the boiler, where the scale accumulates. The scale itself was not really so disadvantageous as was generally supposed. It was, however, desirable that the scale should be removed, because many of the disadvantages, such as straining the seams at the bottom of the boiler, around the furnace angle irons, and other parts where the scale accumulated, were caused by it. The water that Mr. Driffield had given them an analysis of was what they termed "land water." They generally advised, before any of the thousand-and-one nostrums before the public were used, that an analysis of the water should be made. People generally sent their scale to be analysed, which was useless. When they had a sample of the water they knew exactly what to do. With regard to mud cocks, he understood that Mr. Driffield recommended the use of an indiarubber ring. This was scarcely desirable, as he had known of two or three explosions resulting from the use of an indiarubber ring. He knew many firms who simply used a short length of lead piping, pressed out flat, and he knew of lead joints of this nature lasting for many years. With regard to lubricants, they thought that mineral oils might with advantage be used, but not animal or vegetable oils.

Mr. Carey said he must congratulate Mr. Driffield upon his successful summary of a practical experience in the management of boilers. He would also like to ask one or two questions. He concluded, when Mr. Driffield spoke about the quantity of carbonate of soda to be put in a boiler, he specially referred to a boiler evaporating about 35 cubic feet per hour, and working continuously through the 24 hours. Mr. Driffield, also, in referring to his very useful method of preventing the leakage of valves connecting the steam main to the boilers, spoke of a copper pipe one inch in diameter, and said that he had found that it did not fill up with sediment. He would like to ask what length of time he had had those copper pipes? With regard to cross tubes, he would ask Mr. Driffield whether he had found a difference of temperature in chimney gases, leaving a boiler with cross tubes and without? or could give a rough estimate of the comparative efficiency of the two boilers? He thought Mr. Driffield had been unnecessarily modest when he said that he had introduced nothing new on the subject of incrustation, as the points that he had shown about magnesia salts were new and of great practical utility.

Mr. J. W. Macdonald asked how long a boiler would work without sealing in the way recommended by Mr. Driffield, and what thickness of scale would be formed in the time? Also, if he could tell them the proportion there was between the cold feed water and that produced by the condensation of the exhaust steam, so as to find out the reduction of solids in the cold water? He thought a good deal of the apparent reduction (from 37 to 17 grains per gallon) was really due to the dilution produced by the condensed water formed from the exhaust steam.

Dr. Hurter wished to answer Mr. Brunner's remarks as regards the analyses. Mr. Driffield had chosen to give the results of the analysis of the boiler mud in the diagram as percentages. The mud was taken out of the boiler as a thick fluid, and the results were returned as pounds per cubic foot, and would be so expressed in the journal. The analysis of the mud was not complete, and was undertaken simply to confirm the peculiarity found in the scale—viz., that the magnesia was present as hydrate, and not in combination with any acid. The 10 per cent. of silica present in the scale was really chiefly sand. The analysis of the scale puzzled him at first. He had given it to his assistant, who had found it to add up to about 110. He was, therefore, obliged to make it himself, but as long as he calculated the magnesia as carbonate the results were unsatisfactory. In Mr. Macadam's paper there were somewhere about 50 different analyses of boiler incrustations, all adding up to nearly 100, in every one of which the magnesia was stated as carbonate. His (Dr. Hurter's) own investigation proved to him, beyond doubt, that the magnesia was to a great extent in the mud, and wholly in the scale as magnesia hydrate. To him this was news, but, on searching, he found that Professor Voelcker had discovered this fact as long ago as 1867, and that many careful analysts, Dr. Fischer among others, had noticed the same fact. It was a very curious fact, because he had not succeeded in expelling CO_2 from either magnesite or freshly precipitated magnesia carbonate, at the temperature of a boiler in a current of steam. The carbonate of soda, mentioned in the boiler mud, was not in the precipitate, but in solution, and was the excess of soda which had accumulated for a long time in the boiler. It was necessary to ascertain this in order to find what amount of carbonic acid corresponded to the various bases, and whether the magnesia was free as hydrate, or combined as carbonate.

Mr. A. Norman Tate congratulated the Society on having Mr. Driffield there to read his very excellent paper, one which they might take as a type of the papers required by the Society. He was very glad to hear Mr. Driffield mention the difficulties that followed the use of tallow. He had made numerous examinations, connected with boiler-corrosion, of waters from many parts of the world, especially in cases of corrosion of marine boilers: most of these were traceable to the use of tallow introduced into the feed water. He fully agreed with Mr. Driffield that the tallow itself caused much of the mischief, especially that which was sold for lubricating purposes and which was the vilest rubbish ever sold under the name of "tallow." There was no doubt that tallow did combine with magnesia in the boiler, and caused a coating and a considerable amount of corrosion. With regard to the remarks that had been made as to the use of mineral lubricants, it was a curious fact that if tallow were used at the same time with a mineral lubricating oil, the result was often detrimental to both boilers and fittings, although mineral lubricants of themselves might be innocuous. With reference to magnesia, some time ago he had occasion to examine some water in connection with the breakdown of some half-dozen boilers. They had broken down very rapidly. A change of feed water had taken place. The boilers had been worked for from three to four years without difficulty, with the exception of a large amount of scale. That scale, of course, was considered detrimental: the water was therefore changed, and then, after some three or four weeks only, the boilers gave way. In that water over 13 grains per gallon of chloride of magnesium was found, and he had not the slightest doubt himself that it was owing to the decomposition of the chloride of magnesium that corrosion took place. They were greatly indebted to Mr. Driffield for calling their attention to the matter. It was undoubtedly very important that there should not be any chloride of magnesium in feed water. Some remarks had been made with reference to the use of carbonate of soda and caustic soda. It occurred to him that if caustic soda were used after scale had been formed, leakage would most certainly result, because caustic soda so cleared off the scale that faults were made apparent which before were not perceivable. When caustic soda had been used at the starting of a boiler, his experience had been that it had much the same effect as ordinary soda ash.

Mr. W. P. Thompson said that Mr. Driffield had recommended that the return flue should go under the boiler first, before going along the sides. About thirteen years ago he had been asked by a millowner in Derbyshire to examine his boilers. He said that every time they were quiet—say at dinner time—after the first few strokes of the engine the pressure unaccountably and suddenly rose 20lb. or 30lb. He (Mr. Thompson) had examined these boilers, and found that the reason of the sudden change was simply that the centre flues being rather short, and the side flues receiving the hot gases from them being extended above the water line, the upper parts of the side flues got nearly red hot, and the water, previously quiescent, being agitated by the withdrawal of steam, dashed against them and burst into steam quicker than the engine could get rid of it. By altering the flues this was remedied. He thought it frequently happened that flues were built too high, in which case during stoppages of the use of steam they were apt to get over-heated, in which case explosions might ensue through sudden rise of pressure and the weakening of the plates through overheating, especially when the water was low. Bringing the products of combustion under the boiler before allowing them to traverse the side flues, prevented this danger occurring.

Mr. A Watt said, with reference to tallow, that he had had a deposit given to him which consisted of little balls which were composed of tallow and magnetic oxide of iron, which were quite attracted by the magnet.

Mr. Macdonald had once examined a dark mud that had been deposited on the furnace tubes of two boilers, and which seemed to have such great non-conducting properties that the tubes got overheated and soft, so that the internal pressure bulged out the tubes close down to the fires. This mud contained a good deal of magnesia hydrate and carbon, in addition to the lime sulphate, which in this instance did not form a scale. On discontinuing the water which contained the organic matter, the ordinary hard scale formed, and the boilers gave no more trouble. The magnesia was formed from the decomposition of magnesia salts contained in the Thames water, softened by the Porter-Clark process before using in the boilers. The carbon was produced by the decomposition of the organic matter after the long-continued high temperature.

Dr. J. Campbell Brown, before calling on Mr. Driffield to reply to the various speakers, said he was very pleased at the interesting discussion which had ensued, especially from a practical point of view, and he hoped that Mr. Driffield would be induced to follow up the matter, and read another paper next year.

Mr. V. C. Driffield, in replying, said that Dr. Brown had suggested that he should make experiments as to the value of cross tubes. He had often thought of doing this, and would endeavour to carry it out, and would afterwards be glad to place the result before the Society. He felt, however, so sure that his views on the subject were correct, that if he was about to order a new boiler he would certainly order it without cross tubes. Replying to Mr. Carey, he said he had not ascertained whether there was a difference in the temperature of the waste gases on leaving boilers with and without cross tubes, but he did not anticipate that there would be any material difference. He had been asked whether he succeeded in keeping his boilers clean. He flattered himself that he did. Of course they had not the appearance of brand new boilers, but he considered what deposit there was, very trifling. He agreed with what the engineer who spoke (Mr. Ingham) had said—namely, that by far the greater part of the work done in a boiler is done in the furnaces, and upon the furnace plates he practically never found any scale at all. Incrustation takes place most readily where the water is quietest, and hence any deposit there is, is found upon the shell plates towards the back end of the boiler. Even here he did not find it of any very material thickness. Mr. Brunner had asked whether, after all his trouble, the life of the boiler was materially lengthened. He could not say, as he had never had a boiler worn out yet. All he could say was that he believed a boiler was supposed to have done its duty if it worked for 20 years; that they had boilers which had exceeded that age, and that he hoped to get a good many more years of work out of them yet. As to evaporation, he had not come prepared to enter into that subject, but he might say that it amounted to from 6 to 7lb. of water per lb. of fuel. This was, however, a matter which depended upon so many conditions, such as quality of fuel and draught. He thought that the engineer present (Mr. Ingham), who had found fault with his indiarubber ring for the mud-hole joint, must have misunderstood him. He knew perfectly well that, in the case of a mud-hole mounting fixed outside the boiler, where the pressure within would tend to break the joint, an indiarubber ring might be objectionable; but if they would refer to his drawing, they would find that the mud-hole mounting there shown was inside the boiler, and, as it was a spigot joint, the ring could not possibly be blown out. Indeed, the greater the pressure in the boiler the tighter the joint became, and no injury could arise even if the bolts became loose. Mr. Carey asked if the quantity of soda suggested applied to an evaporation of 35 cubic feet of water per hour. It did; but, of course, if the boilers did not evaporate so much, the quantity would be reduced. As to the method of coupling the junction valves with the copper drain pipes, he could give it a three years' character, and he thought that was long enough to prove pretty positively that it was satisfactory. A remark had been made about the condensation of exhaust steam in the water heater which was to the point. This he felt he had overlooked. He could not say, without inquiry into the matter, what proportion of the water supplied by the heater was due to condensation, but it was part and parcel of the benefit of the heater that, whether by condensation or otherwise, it did reduce the solid matter contained in the feed water.

The Chairman said probably the Society would remember that last month it was arranged that questions should be sent out to Dr. Archbold regarding his paper on "Starch Manufactures." This had been done, and they had his reply, which was as follows:—

DR. ARCHBOLD'S REPLY TO THE DISCUSSION ON HIS PAPER ON "STARCH" (Read at the February Meeting of the Liverpool Section).

	1st.	2nd.	3rd.
Starch	98·5	92·88	20·33
Gluten Cellulose	—	2·38	1·25
Ash	0·3	0·60*	3·65*
H_2O	1·2	1·11	1·77
	100·0	100·00	100·00

What is meant by the three grades of starch obtained from the three separate runnings will be clearly understood from the above analyses, which represent average analyses of these starches as taken from the kiln. In the first running there is a large body of starch separated from the albumenoids, &c., and the latter being heavier and denser, quickly subside, leaving the upper stratum of nearly pure starch, which is run off with greater facility, and free from the impurities. The second and third grades, on the same treatment as second and third runnings, contain much of the above perfectly separated starch, mixed with that less perfectly separated, the globules of starch having more or less particles of albumenoids and cellulose adhering to them, the resulting starches being more or less coloured, while the first is perfectly snow white. These grades generally come under the designation of "manufacturers' starches," and are used principally by paper makers, dyers, &c., and in commerce usually contain 18 to 20 per cent. of water. The ash, as will be seen, is high; however, that is generally due to free alkali. Regarding the formula of starch, I should like to dwell at great length. However, in this reply, I must be brief, as time prevents me going further into detail. Dr. F. Salomon made numerous experiments on potato starch, which have been corroborated by myself on corn starch, which go to prove that its empirical formula is $C_6H_{10}O_5$, or some multiple of it $(C_6H_{10}O_5)_2$. Starting with the elementary composition of starch and the formation of dextrose according to the equation $C_6H_{10}O_5 + H_2O = C_6H_{12}O_6$; that is, 100 parts anhydrous starch = 111·11 parts of anhydrous dextrose. Therefore, in the complete saccharification of starch (= to 100grms. anhydrous starch) the yield was found to be (from an average of over 100 such experiments, and the sugar estimated by Allihon's method) equal to 111·11grms. dextrose, by sp. gr. 111·11grms. dextrose, and by optical method 111·11grms. dextrose; thus confirming the formula of $C_6H_{10}O_5$.

ON THE DIGESTIVE FERMENTS.

BY F. BADEN BENGER, F.C.S.

At the request of several members of the Committee of this Section of the Society of Chemical Industry, I have undertaken to read a short paper on the digestive ferments, and to give some illustrations of the action of these ferments on articles of food. I at first hesitated very much to pose before you in the position of one who presumably has something new to say—when I have so little—but I was reminded that this particular branch of physiological chemistry is probably rather outside the field of observation of most members of the Section, although many of the experiments I have to show you are in reality performed daily by each one in his most private laboratory—his stomach. These are the considerations which led me to attempt the task of interesting you for a very few minutes this evening.

The study of these digestive processes has naturally attracted the attention of many eminent men. In this country one of the most recent, and certainly the most distinguished investigator, has been Sir Wm. Roberts, M.D., F.R.S., of this city, and to his researches I am indebted for much that I have to bring before you.

Digestive ferments is the name given to certain principles secreted at different points in the alimentary canal, their office being to transmute the food we eat into products capable of being assimilated, and so used in the building up of our tissues, or in supplying the necessary fuel required to maintain the continuous working of our several functions. Speaking generally, these ferments have the power of increasing the solubility and diffusibility of food—for instance, starch is converted into sugar (maltose), and albumen into peptone. The changes brought about are not, chemically speaking, complicated, though the physical condition of the substance acted on is often entirely altered. The actual ferments themselves have never been absolutely isolated. It is known, however, that they are albuminoid, or are invariably associated with albuminoid matter: they are soluble or unorganised, as distinguished from the organised and insoluble ferments, such as yeast. They are precipitated from watery solution by alcohol, but even prolonged contact with this fluid does not injure them. When the alcohol is removed, their solubility and activity are found to be unimpaired. They are destroyed by many chemical reagents, and when in solution they are coagulated and rendered permanently insoluble and inactive by a temperature of about 75° C. They have no power of self-multiplication or growth of any kind, as is the case in the class of so-called organised ferments, but their action is quite distinct from what we understand by chemical, in the ordinary sense of the word. I shall presently have the opportunity of illustrating my meaning by an experiment. A special interest attaches to these principles from the fact that they play so important a part in our individual organisms. Their origin is shrouded in mystery, they are formed under the influence of vitality, and seem indeed to be a remnant of unexpended vital force.

The importance of preparations of these ferments in modern civilised life is considerable; some of them are largely used in medicine, and others are employed in the manufacture of peptonised or partially digested foods.

The first of the secretions with which our food is brought in contact in the process of digestion is the saliva. One of the purposes served by saliva is to lubricate the morsels of food, and so facilitate their being swallowed, and this probably is the extent of its service with regard to meat, and many other articles of diet; but saliva contains a very important ferment—ptyalin. This body may be precipitated in an impure condition by adding filtered saliva to strong alcohol. Its action on cooked or gelatinised starch is similar to that of malt diastase, converting it into dextrine and sugar. Starchy foods, of course, form a very considerable part of the diet of man. The importance of ptyalin can, therefore, be well understood, especially when it is known that starch is not acted on by the juices of the stomach, and that it is not until it reaches the duodenum that farinaceous food is again brought under the influence of a starch digesting ferment. It is essential that the starch should be cooked, as raw or unbroken starch granules are scarcely acted on at all by the saliva of man, though the lower animals are capable of digesting it. I have here a small quantity of ptyalin, and if I add a little to this test tube full of warm starch mucilage, you will observe that a change will shortly take place. The change is much more rapid if saliva is used, as the ptyalin is then in solution, and a few seconds will be required to bring the ptyalin to the same condition. The first step in the digestion of starch is the formation of soluble starch; a bright transparent solution is obtained which still gives the blue reaction with iodine; then dextrines are produced, yielding brown and yellow reactions with the same reagent; and finally sugar, yielding no colouration with iodine. This digestion of starch by ptyalin can take place only in alkaline, neutral, or faintly acid media. The juices of the stomach during digestion are acid, but it seems probable that masses of bread and other farinaceous food, saturated with saliva, would continue for a time to be acted on by the ptyalin after they reach that organ, as they could hardly be immediately permeated by the gastric juice.

We now come to the digestive ferments of the stomach. These are pepsin and a curdling ferment, the active principle of the well-known rennet used in the manufacture of cheese. Pepsin is the agent by which albuminous matter or proteids, such as meat, eggs, etc., are converted into soluble peptones in the stomach, and thus fitted for absorption. Though not absolutely inert in neutral media, it is practically so. The normal acidity of the gastric juice is equal to about 0·2 per cent. of HCl., and though it is probable that during the digestion of meat, etc., other acids are set free from salts contained in the food, hydrochloric acid is found to be the one secreted with pepsin in the gastric juice. Water containing 1 per cent. of strong hydrochloric acid is a suitable medium for experiments with pepsin.

Pepsin, like all the digestive ferments, is soluble in water or glycerin. From an aqueous extract of the mucous membrane of the stomachs of animals, it may be precipitated in various ways—perhaps it would be more correct to say that precipitates may be obtained in which the presence of pepsin can be demonstrated by its digestive power. But actual pepsin has never been isolated, and attempts to purify the precipitate are very apt to lead to great diminution in its activity. The mucous membrane does not always yield an active extract. The pepsin is sometimes incompletely formed. It may exist as what is called pro-pepsin or pepsin-precursor, and time, aided by atmospheric influences, may be necessary in order to develop the perfect ferment.

The Pharmacopœia process for preparing pepsin is the somewhat rough-and-ready one of scraping the cleansed mucous surface of the stomach of the pig with a blunt knife; the matter thus removed is dried at a temperature not exceeding 120° F., and powdered. Carefully prepared, this is a fairly active product; but the best that can be said of it is that it contains the proteolytic ferment of the stomach mixed with much undesirable animal matter, extremely liable to decomposition. I once asked a candidate at an examination of the Pharmaceutical Society how to make Pharmacopœia pepsin, and he told me it was done by scraping the outside of a sheep after the removal of the skin. I have examined some specimens of pepsin which may have been prepared by this method.

Some commercial pepsins are prepared by precipitating aqueous extracts of the mucous membrane of the pig or sheep, the precipitate is commonly mixed with starch powder or sugar of milk. Fluid preparations are, however, now much used; but by whatsoever process pepsin is prepared, the only test of its quality that can be applied is the measure of its digestive power. The mode of applying this test, adopted in the last edition of the "British Pharmacopœia," is one proposed by myself in a paper read before the British Pharmaceutical Conference, at its York meeting in 1881. The official direction is as follows:—"Two grains of it with an ounce of distilled water, to which 5 minims of hydrochloric acid have been added, form a mixture in which at least 100 grains of hard-boiled white of egg, pressed through wire gauze of 36 meshes to the linear inch, and made of No. 32 brass or copper wire, will dissolve on their being well mixed, digested, and well stirred together for 30 minutes at a temperature of 130° F."

In previous editions the white of egg used was ordered to be in thin shavings, the temperature 98° F., and the time "about four hours." The test was tedious, the condition of the egg not precisely indicated, and the element of time more or less variable according to the meaning attached to the word "about."

My original paper contains some details of manipulation necessarily omitted from the brief Pharmacopœia directions. In practice I find that the white of egg having been pressed through the wire gauze and weighed, is best lightly rubbed in a glass mortar with the acidulated water: this separates the vermiform particles, which cannot be satisfactorily accomplished by mere stirring; this is, of course, most important, as the amount of albumen dissolved, other things being equal, will depend on the amount of surface presented to the action of the ferment. The mixture is then poured into a large test tube and floated in a beaker of water. Half-a-dozen such tubes, numbered, and each containing 100 grains of hard-boiled white of egg and 1oz. of acidulated water, can thus be floated in the same water-bath, and the same number of examples of pepsin or preparations of pepsin can then be tested under absolutely identical conditions. This latter point is most important in comparative experiments, for it must be remembered that the digestive power of pepsin is greatly influenced by many circumstances, the degree of subdivision of the egg, the temperature of the mixture, the volume of the solvent, and the frequency with which the mixture is stirred. Having floated the charged test tubes in the beaker, as shown on the table, and provided each tube with a small glass stirrer so that pepsin may not be transferred from one tube to another, the heat of the spirit lamp or Bunsen's burner is applied until the temperature of the whole has reached 130° F. There is no practical difficulty whatever in this, and any slight variation of temperature effects all the tubes alike, so that the value of the test for comparative experiments is not influenced by slight variations.

The samples of pepsin or its preparations having been previously weighed or measured, are now added to the tubes and the temperature maintained as nearly constant as possible, care being taken that it does not rise above 130° F. The contents of the tubes should be stirred at regular intervals, say every five minutes, and in half-an-hour the albumen should have dissolved. The glass water-bath is more convenient than the ordinary water-oven or incubator, as it enables the operator to see the progress of the experiment, and in practice it is often easy to select the best sample of pepsin in a few minutes.

It will, of course, be noticed that the temperature employed in this artificial stomach is much higher than that of the body. It was adopted because it was found that about 130° F. is that of the maximum activity of pepsin, and experiments had shown that specimens of pepsin which were most active at the higher temperature, were invariably the most active at the temperature of the body (98° F.), whilst the adoption of the higher temperature enabled the operation of testing to be accomplished in half-an-hour instead of occupying four hours, as in the previous edition of the Pharmacopœia.

Some may perhaps be asking themselves the question, How can a dose of pepsin which requires 20 or 30 minutes to digest 100 grains of egg at 130° F., have any appreciable effect on a meal when taken as a digestive?

In answering this, we must not forget the fact that whilst in our laboratory experiments the products of digestion remain in the digesting apparatus to gradually retard, and finally stop, the action of the ferment, in the stomach these products are constantly removed as digestion goes on. It must not be supposed that 100 grains of egg albumen is all that 2 grains of B. P. pepsin, or the minimum dose of a fluid preparation, will digest in half-an-hour under other conditions and with other surroundings. The following experiment (described by me in *The Lancet* of 3rd April, 1886) will demonstrate the contrary. I took ten times the Pharmacopœia quantity of egg and acidulated water—that is, 1000 grains of egg and 10 fluid ounces of water; these were placed in a beaker; 100 grains of egg and 1oz. of acidulated water were put in a test tube and stood in the beaker, and the whole heated to 130° F. A teaspoonful, the minimum dose of an active fluid preparation of pepsin, was then added to both beaker and test tube, the temperature maintained constant, and the contents of both stirred occasionally. When the egg in the test tube had all dissolved, which in this experiment occupied 25 minutes, the contents of the beaker were thrown into a fine muslin filter and drained; the undissolved egg weighed 220 grains. Here, then, a small dose of pepsin had dissolved 780 grains of egg in 10 ounces of fluid, whilst a similar dose had dissolved 100 grains in 1 ounce of fluid. Another attempt was made to approach more nearly to the conditions under which pepsin acts in the stomach. The egg, acidulated water, and pepsin were placed in a parchment dialyser and floated on a bowl of acidulated water. In this case it was found, also, that enormously more egg was dissolved in the dialyser where the products of digestion could diffuse away, than in a test tube containing a similar mixture.

Each of the two beakers on the table contained, this afternoon, 1000 grains of hard-boiled white of egg and 10 ounces of acidulated water. To one I added a teaspoonful of an active solution of pepsin, and maintained it at a temperature of 130° F. for half-an-hour—you will observe that the white of egg has disappeared, and it now exists as peptone, or peptones, for there are several—in solution, and the presence of this peptone can be easily demonstrated by a colour test. When a solution of peptone is rendered strongly alkaline with potash, and a few drops of Fehling's copper test are added, a beautiful rose colour is produced. I will apply this test to a portion in a test tube.

The second ferment contained in the gastric juice is that known as the curdling ferment, and is familiar to all of us as the active agent in rennet. Its sole property, as far as is known, is to curdle milk, to cause a separation of the casein, though it is probable that it serves some other purpose. If it were found only in the stomachs of milk-consuming animals, we might rest on the supposition that it is merely a milk curdler, but Sir Wm. Roberts has obtained it from the digestive organs of the fowl, and I have myself extracted it from the stomach of the cod-fish. Now, neither of these creatures can possibly require the services of a milk curdler. The curdling power of gastric juice was long considered to be due to pepsin, but it is now known to be caused by the presence of a distinct ferment. If the mucous membrane of the stomach of the calf be macerated in a saturated solution of common salt, an extract is obtained practically destitute of proteolytic power, but extremely active as a curdler. If I add a few drops of this solution to a beaker of warm milk (about 100° F. is the best temperature), and stir them together, we shall see that in a few minutes the milk will solidify in a characteristic manner—a solid jelly-like mass being produced. If this be now broken up with a glass rod, the casein, or curd, will shortly contract, and form lumps floating in the whey. Much of the fat of the milk is entangled with the caseïn in these masses, and the whey is chiefly a solution of the lactose, or sugar of milk, and the salts.

The ferments of the pancreas or sweetbread have not, until recently, attracted much attention, and the remarkable digestive power of the pancreatic juice was scarcely suspected. Three of these ferments are known to exist: an amylolytic or starch-digesting one, resembling ptyalin in its power of converting starch into sugar, a proteolytic or proteid digesting one called trypsin, and another curdling ferment. The ferments of the pancreas, like those of the stomach, have not yet been absolutely isolated; they may be extracted from the minced pancreas by similar solvents, water, or glycerin—and here, again, the same difficulty is experienced as in extracting the ferments from the mucous membrane of the stomach. The gland may contain no completely formed ferments. They may exist as zymogen, or mother of ferments, and our solutions may prove inactive until the perfect ferment is developed.

I am not aware of a process by which they can be entirely separated from each other. I have obtained by fractional precipitation from aqueous solutions with strong alcohol, precipitates possessing respectively very much more of the diastasic and of the tryptic ferment, but have never completely separated them. Like the peptic ferments, they are very easily destroyed, and the utmost care is necessary in their preparation.

I have here a solution of these pancreatic ferments, and will first give you an illustration of its starch-digesting or diastasic power. This beaker is filled with warm thick starch mucilage. If I add a little of the solution and mix it with the starch paste by stirring, you will notice a rapid change in the contents of the beaker—they quickly become thin and transparent. I can now pour them from one beaker to another like water. If we now apply the well-known iodine test for starch to a portion, we shall still get the blue colouration—the starch has for the most part been merely converted into the soluble modification, but the digestive process is going on, and in a short time we should get the brown, and then the yellow, reaction of the dextrines; but to save time I will add a little more of the pancreatic solution — now iodine no longer produces a blue reaction — the starch no longer exists as starch, but as dextrine A few more drops are added, and now no colour is produced by the addition of iodine; the starch has been transmuted into sugar (maltose). The rapidity of this transmutation depends upon the proportion of ferment to starch. It is easy to produce the change almost instantaneously. If I half fill this test tube with the pancreatic solution, warm it slightly, and add a drop or two of the starch mucilage, I cannot apply the iodine test in time to catch a molecule of the starch unconverted. This illustrates the peculiar action of the ferments, to which I referred early in my paper. This change from starch to sugar can be produced almost as rapidly as the neutralisation of an acid by an alkali; but, on the other hand, if the proportion of ferment to starch be small, many hours may be required to effect the transformation; or, if still smaller, the ferment may exhaust its energy before the whole of its work is accomplished. Sir William Roberts, in his Lumleian Lectures, gave a very graphic illustration of this action. "There is," said he, "something in this, strikingly suggestive or reminiscent of the action of living organisms. To illustrate my meaning, let us compare the particles of the ferment to a band of living workmen, whose function it is to scatter little heaps of stones. If the heaps are few, and the workmen many, all the heaps will be scattered at once, and the energy of the workmen will remain sensibly unimpaired; but if the heaps are millions, and the workmen hundreds, and if the workmen are doomed to labour on until they fall exhausted at their task, the scattering of the heaps will go on for a comparatively long time, and the process of exhaustion will be a gradual one."

We will now turn to the proteolytic or proteid-digesting ferment of the pancreas, trypsin. It will be remembered that the proteolytic ferment of the stomach, pepsin, is practically inactive in neutral solutions, and is destroyed by alkalis. Trypsin, on the other hand, is active in neutral and alkaline solutions, and inactive in more than feebly acid media. An alkalinity equal to about 1 per cent. of bicarbonate of soda, seems the most favourable, however, to its full action. Its digestive power is exercised less rapidly on coagulated white of egg or fibrin than is that of pepsin. The casein of milk, however, is much more rapidly digested by the pancreatic than by the peptic ferment, and therefore affords us a convenient means of illustrating its action.

I have here two beakers filled with slightly-diluted milk. To one has been added a teaspoonful of the same solution of the pancreatic ferments used to demonstrate the action of the amylolytic or diastasic ferment, and the mixture has been kept at a temperature of about 55° C. for half-an-hour. There is very little alteration in the appearance of the milk. It is a little yellower; but a few tests will show that the casein has disappeared, and peptone has taken its place. I will pour some of the milk from each beaker into these test glasses, and add a little dilute acetic acid. In the peptonised or digested milk no precipitate is produced, but in the other the casein is, of course, precipitated. If we take two other test glasses of the peptonised and unpeptonised milk, and apply the test for peptone used just now, solution of caustic potash and a few drops of Fehling's copper test, we get the rose-red colouration instantly in the peptonised milk, but none in the other.

During the transformation of casein into peptone, an intermediate body called meta-casein is first formed. This is distinguished from ordinary casein by its property of coagulating on boiling. Ordinary milk can, of course, be boiled without change, but if we boil milk which has been submitted—for a few minutes only—to the action of a small proportion of the pancreatic ferment, and which is thereby partially peptonised, an abundant curdy precipitate is formed. This, however, can be entirely prevented by previously rendering the milk slightly alkaline; about 1 grain of bicarbonate of soda to the ounce of milk is sufficient to prevent the precipitation of meta-caseïn on boiling. That this does not prevent its formation can be shown by neutralising a portion of alkaline milk at the proper period of digestion, and immediately boiling it, when the meta-caseïn will be thrown down as before.

We may illustrate the wonderfully rapid action of trypsin somewhat in the same way that we did the amylolytic ferment of the pancreas. I mix in this test tube a little pancreatic solution, water, and milk; it is even unnecessary to warm them. If, now, I apply the peptone test, the rose-coloured reaction is produced; some of the casein has already been converted into peptone.

By adding a solution of the pancreatic ferments to a large excess of strong alcohol, a white precipitate is formed, possessing both the amylolytic and proteolytic power of the original solution. I have some of this precipitate in my hand. It has been dried at a low temperature, and its activity is very remarkable. If I take a small fraction of a grain of it on the point of my penknife, and stir it into this beaker of warm starch mucilage, you will observe in a few seconds that a change is going on; the mucilage has become thin and clear, the starch is rapidly undergoing transformation into dextrine and sugar. Its action on milk, too, is similar to that of the pancreatic solution, from which it is precipitated. The pancreas contains yet another ferment, one capable of coagulating milk in a very similar manner to the curdling ferment of the stomach or rennet, but differing from it in this respect:—Rennet will coagulate neutral or very feebly alkaline milk, but alkalinity produced by a grain of bicarbonate of soda to the ounce of milk is sufficient to prevent it. The curdling ferment of the pancreas, however, is unimpaired by an alkalinity three or four times as great, so that the two ferments cannot be identical. It is singular that, until comparatively recent times, the only function attributed to the pancreatic juice was the digestion of fats, and yet to-day it is the one that is questioned. It is one I have never obtained satisfactory evidence of, and am, therefore, unable to demonstrate to you.

In testing preparations of the pancreatic ferments we have again to rely, as in the case of pepsin, on the measurement of the work they are capable of performing. In an elaborate paper read before the Royal Society, London, Sir Wm. Roberts describes a method of accomplishing this. In the case of the amylolytic ferment, it is based on "the quantity of starch mucilage of known strength, which can be transformed by a unit measure of solution of the ferment to the point at which it ceases to give a colour reaction with iodine in a unit of time, and at a fixed temperature." The proteolytic ferment is estimated in a similar manner, except that milk is used instead of starch mucilage, and the indication or end-reaction of the experiment is the precipitation of meta-casein on boiling a portion of the milk.

A knowledge of the temperature at which the maximum activity of these ferments occurs is important in their practical application to the production of peptonised or partially peptonised or digested foods. The activity of the diastasic or amylolytic ferment commences a little above the freezing point, and rises gradually with the temperature until 30° C. is attained; it then remains stationary until 45° C., and then gradually falls with the further rise of temperature, until at 65° C. it ceases to act.

The activity of the tryptic ferment rises gradually with the temperature until 60° C. is reached, and then rapidly falls until at about 75° C. it becomes inert.

Peptonised or partially peptonised milk, and other articles of diet, are very largely used at the present time in rearing infants, and by invalids unable to digest ordinary food.

Fully peptonised milk has a slightly bitter taste, which is unobjectionable to many, and which may be covered by the addition of a little coffee. It is, however, seldom necessary to fully peptonise articles of food, and partially peptonised milk scarcely differs in appearance or taste from ordinary milk; nevertheless it has been very considerably modified. Its undigested caseïn cannot be curdled by the acid juices of the stomach into tough compact indigestible masses, but forms on the addition of acid light flakes, which are much more easy of digestion.

In preparing this partially-digested milk, the following points should be borne in mind: 1st, The milk should be diluted with a fourth, or, better, with a third of its bulk of water. This entirely prevents the action of the curdling ferment of the pancreatic solution. 2nd, The temperature of the milk should be from 50° C. to 60° C., at which the tryptic ferment attains its maximum activity; and 3rd, That if the milk be not consumed by the infant or invalid as soon as it is sufficiently peptonised, it must be rendered slightly alkaline by the addition of about one grain of bicarbonate of soda to the ounce, and boiled up to put an end to the action of the ferment, the addition of soda being then necessary to prevent the precipitation of meta-casein. It is preferable, when convenient, to use the partially-peptonised milk unboiled with the ferment still active. Many other articles of food are peptonised in a similar manner—soups, beef tea, farinaceous gruels, etc.

We must content ourselves on this occasion with the mere mention of the remaining ferments concerned in the digestion of our food. Bile is said to assist in the emulsifying of fats, and the intestines secrete a ferment which changes cane sugar into invert sugar. Such, gentlemen, is the very hurried sketch of the principal digestive ferments which the limited time at our disposal this evening permits, and I feel that my apologies are due to you for having attempted to traverse so wide a field.

◆

A DISCHARGE FOR MANGANESE BRONZE IN CALICO PRINTING.

BY JOHN RILEY.

The manganese bronze of the calico printer is an oxide of manganese. It is obtained on cotton cloth by passing the cloth through a moderately strong solution of a salt of manganese, precipitating the monoxide by means of caustic soda, and converting this monoxide into a higher oxide by means of oxidising agents, such as bichrome and bleaching liquor.

The style was first introduced by the late Mr. John Mercer, in the year 1823.

The discharging agent in use at the present time is stannous chloride. When a solution of this compound is printed upon manganese bronze and steamed, a double decomposition takes place; oxide of tin is fixed upon the cloth, and the chloride of manganese which is formed is washed away by a passage through water.

The number of colours which can be associated with stannous chloride is limited, and some of those which are used are not altogether satisfactory as regards fastness against light and soap.

In my endeavour to discover a discharging agent which could be used in conjunction with more permanent colours, I found that the sulphocyanates (commonly called sulphocyanides) had a considerable reducing action upon the manganese bronze. I first observed this property in December, 1883.

I was rather surprised when reading quite recently the "Life of John Mercer," published a few months ago, to find that Mercer had observed and applied this property of the sulphocyanides. The following is an extract from the biography referred to:—

"One of his (Mercer's) applications of the sulphocyanide (mixed with a little sulphuric acid) was for discharging manganese bronze without injuring blue, or interfering with subsequent dyeing with madder, logwood, etc."

At the time referred to, the pieces, after printing, were hung for a day or two to give the reducing agent time to act; steaming was not applied in the production of this style until within a comparatively recent period.

I cannot say whether or not this information was ever made public prior to the publication of this book; if it has been, I have never come across it.

I was desirous to find out a discharge that could be used along with pigment colours, which are fixed by means of albumen. The mixture of sulphocyanide of potassium and sulphuric acid as used by Mercer will not do for such colours.

I discovered a mixture that can be employed perfectly well with albumen, and which discharges the bronze completely when steamed for one hour in Smith's continuous steaming machine. I had hopes that this discharge would prove of considerable practical value, but up to the present time those hopes have not been fulfilled. To obtain a good discharge it is necessary to add 1⅛lb. ammonium sulphocyanide and 3lb. of ammonium chloride per gallon of colour. These salts are hygroscopic and under the influence of the steam, the discharging materials swell beyond the legitimate limits of the object printed. If a pigment colour, such as vermilion or ultramarine blue, is used along with the discharge mixture, a white bondage is visible round the red or blue object. In printworks phraseology it would be described as "bleeding." This is a very serious fault, and until it is remedied the discharge will be of little practical use.

Steaming in the box at 1lb. pressure gives a neater mark, but the discharge is not so perfect. Insoluble sulphocyanide of lead and ammonium chloride give a better result, but the bleeding is not entirely done away with.

Potassium sulphocyanide does not discharge quite so well as the ammonium sulphocyanide.

Ammonium sulphate may be substituted for ammonium chloride without any appreciable difference. There is no weakening of the fibre by this method of discharging the bronze.

I cannot give a satisfactory explanation of the chemical changes which occur in the discharge under consideration. I presume that the sulphur of the sulphocyanide is converted by the peroxide of manganese into sulphate of manganese, but the functions of the ammonium chloride I cannot explain.

The ammonium sulphocyanide itself discharges to some extent: in fact, I believe that a very strong solution of this compound would completely discharge the bronze.

Ammonium chloride discharges only to a slight extent, but it assists the ammonium sulphocyanide very materially.

DISCUSSION ON DR. G. H. MORRIS'S PAPER.

Dr. Tilden said he had great pleasure in expressing his gratification at what they had had an opportunity of listening to. It might not, perhaps, be known to the meeting that Dr. Morris has paid a visit to Copenhagen, and has there studied the process in Dr. Hansen's laboratory. Whilst one felt how exceedingly wide the subject is, he took it that most chemists are beginning to understand that they will have to make themselves acquainted with the conditions of growth and development of micro-organisms and the chemical changes they bring about. They had only to recall a number of quite familiar transformations, such as nitrification, which at one time were supposed to be purely physical or chemical, but which are now known to be effected through the agency of minute forms of life. Dr. Morris had referred throughout solely to the process by which the organisms are isolated one from another, and he had referred exclusively to the changes which the organisms themselves undergo; but, of course, there was another part of the question, which he supposed would not be neglected. And he would be glad to learn from Dr. Morris whether any systematic work is going on as to the action of yeast or other organisms on chemically pure materials? They were a long way off knowing exactly what are the constituents of a wort, but if they knew the effect of yeast on solutions of pure sugars they should have made an important step forward; and he would like to know whether systematic experiments were likely to be undertaken on a large scale? as this was surely a subject which ought to occupy the attention of all practical men.

Mr. Collins said he understood Dr. Morris to say that several of the yeast cells have different powers of attenuation. He would be glad to know if this was the same for the yeast used in this country, and whether the different powers of attenuation were caused by the yeast acting in a different manner?

Dr. Morris: With regard to the question asked by Mr. Collins, he might say that so far as the experiments had been carried, the differences of attenuation given by different cultivated yeasts were as marked as those with the pure Carlebery yeasts. With reference to Professor Tilden's remarks, experiments had recently been made by Bourquelot on the action of yeast upon certain carbo-hydrates, and with what was known as "German yeast." Had the experiments been carried on with pure yeast they would have thrown considerable light upon the action of the yeast upon carbo-hydrates. It was, however, shown that the rate of fermentation depended upon and was proportional to the rate of diffusion of the carbo-hydrates through the cell-wall. With regard to the action of yeast upon pure solutions he could only say that he had given a brief summary of what had been done, and he had no doubt that before long they should have the whole of the subject of the fermentation of the various carbo-hydrates by pure yeast thoroughly examined. Of course, in a thing of that kind it was not the work of a day; it required a very lengthened series of experiments, and he was afraid it would be some considerable time before they were able to say what the action of pure yeast upon the various constituents of malt-wort was, but when they were able to do so it would doubtless throw a very great light upon the question of fermentation.

MR. J. NEILSON CUTHBERTSON IN THE CHAIR.

INDICATORS IN VOLUMETRIC ANALYSIS.

BY R. T. THOMSON.

About four years ago I began a comparative study of the characteristics and behaviour of litmus, methyl orange, phenacetolin, and phenolphthalein as indicators in volumetric analysis, and in four subsequent papers these observations were extended to rosolic acid and lacmoid. In the following paper I propose to bring the same tests to bear on turmeric, cochineal, dimethylamidoazobenzene, and Congo red, and in a general way to institute a comparison between these indicators and those which were formerly examined. Before proceeding, it will be well to make a remark regarding the end-point of the reaction, or shortly end-reaction, which occurs in titration. I have rejected indicators in cases where the end-reaction was doubtful or obscure, so that the change in colour was not reasonably sharp, but was gradually developed. It is right to make this point clear, as other observers seem to be satisfied with end-reactions which, in my judgment, ought not to be relied on. In certain circumstances we may be compelled to content ourselves with approximate results, but we must not flatter ourselves that anything like desirable accuracy has been attained.

Turmeric.

Little information can be gathered with regard to turmeric paper, beyond its delicacy as a test for free alkalis and alkaline earths, especially hydrate of barium, and its special application to the detection of boric acid. The yellow turmeric paper employed in the following experiments was prepared according to the directions in Sutton's "Volumetric Analysis." Besides this, a red-brown paper was made by adding sufficient dilute caustic soda to the alcoholic turmeric solution, and passing slips of filtering paper through it. This paper, when dried, is of a light reddish-brown tint, but when wetted with pure water this is intensified to a dark red-brown colour. When partly inserted in a very dilute solution of an acid, the portion immersed becomes bright yellow, while immediately above this a moistened dark red-brown band is formed, and the upper dry portion retains its original colour. This phenomenon only occurs in the titration of a comparatively large proportion of an acid, when the latter is nearly all neutralised, and thus serves to indicate the near approach of the end-reaction. When neutral or alkaline, the colour of the immersed portion of the paper is simply intensified in the manner already described. This intensification is quite as decided as a transformation of tint would be.

Passing over any details with regard to the hydrates of the alkali and alkaline earth metals, the first substance to present itself for consideration is—

(1) *Ammonia.*—Several experiments brought out the fact that only about 97 per cent. of the ammonia present could be determined with turmeric paper as indicator, and further, that the end-reaction was an extremely indefinite one. In this respect turmeric agrees with phenolphthalein, and, like it, is absolutely useless in the determination of ammonia, or for any estimation in which that compound, or salts derived from it, is present.

(2) *Carbonates and Sulphide of Alkalis.*—On titrating carbonate of sodium with sulphuric acid, taking care that no loss of carbonic acid occurred, the change in colour of the yellow turmeric paper became gradually less marked, until when about 51 per cent. of the soda had been converted into sulphate, and the other half had formed bicarbonate of sodium, the solution showed a tendency to turn the red-brown paper yellow. The point at which the latter compound is produced cannot, however, be arrived at with anything like precision, even when small quantities of the salt are operated upon. In the latter circumstances phenolphthalein gives a fairly good end-reaction at the same stage of the titration, and in this shows its superiority to turmeric. In normal sulphides half the base is determined, but the same remarks apply to the behaviour of turmeric with these compounds as with the carbonates.

(3) *Thiosulphate, Sulphite, and Phosphates of the Alkalis.*—The first-named of these compounds is neutral to turmeric, as it is to all the other indicators I have examined. The normal sulphites of potassium and sodium (Na_2SO_3), and the mono-acid phosphates of these metals (Na_2HPO_4), are nearly neutral, or more correctly, slightly alkaline. In this respect turmeric resembles phenolphthalein, but the latter gives a sharp end-reaction, while with the former the neutral point is so ill-defined as to be valueless.

(4) *Silicate and Borate of the Alkalis.*—In ordinary silicate of sodium ($Na_2Si_4O_9$) about 90 per cent., and in borax ($Na_2B_4O_7$), about 50 per cent. of the total soda can be determined with sulphuric acid when turmeric paper is employed as indicator. The end-reactions are eminently unsatisfactory, as is also the case if phenolphthalein be substituted for turmeric.

So far, turmeric shows little utility as an indicator, but we have still to glance at its chief claim to favourable consideration, which rests on its delicate indication in the determination of organic acids with caustic soda or potash.

(5) *Determination of Citric Acid.*—Four years ago I showed that phenolphthalein was the only perfect indicator for this purpose, and that even litmus and rosolic acid, leaving aside their objectionable end-reactions, were rendered unfit for use owing to the fact that they show a distinct and measurable alkalinity in normal citrate of sodium. Since then turmeric solution has been proposed by F. Watts, especially for dark coloured solutions. His method is to spread it in thin films on a white plate, and to transfer a drop of the titrated liquid upon one of these films, in order to find the point at which the end-reaction is reached. I am convinced, however, that the red-brown paper I have described is both more sensitive and serviceable than the solution used in this way. In several experiments made with 25cc. of $\frac{n}{5}$ citric acid, exactly 25cc. of $\frac{n}{5}$ caustic soda were consumed in each case, and the red-brown paper ceased to acquire a yellow tint at exactly the same point as phenolphthalein showed a faint alkaline reaction.

In the determination of acetic, tartaric, oxalic, lactic and succinic acids, turmeric paper is equal in precision to phenolphthalein, and can be used in very dark-coloured solutions, where the latter could only be employed after large dilution.

Owing to a distinct alkalinity of normal soaps and an unsatisfactory end-reaction, turmeric paper cannot be substituted for phenolphthalein, even in the few cases where it might be useful in the estimation of free fatty acids or the saponification equivalent of oils.

An excellent feature in red-brown turmeric paper, and a quality which it possesses in common with phenolphthalein, is its power of detecting small but determinable proportions of acid in strong alcohol. Particular care must be exercised in judging the neutral point, especially on the near approach of the end-reaction, as the colouring matter is partially dissolved. Even the most delicate litmus paper cannot accomplish this occasionally useful result; and fails to detect, for example, 0·03 per cent. of acetic acid in a 90 per cent. spirit, unless the alcohol be expelled from the paper after immersion. I formerly showed that the inability of lacmoid paper, to indicate the presence of comparatively large proportions of acids, was much more striking than that of litmus.

On the whole, turmeric, though not so widely applicable as phenolphthalein, is worthy of consideration as a useful adjunct to the latter indicator. It provides us with a paper which is more reliable than litmus in the titration of solutions containing citric, acetic and succinic acids.

In both phenolphthalein and turmeric, and especially as regards the former, the chief weakness lies in their peculiar susceptibility to the disturbing influence of the normal salts of ammonium. In consequence of this, the sphere of their application is considerably contracted. An indicator possessing the general properties of phenolphthalein, but not exhibiting this imperfection, is still a desideratum.

Cochineal.

In the determination of pure alkalis and alkaline carbonates and sulphides, cochineal solution gives accurate results and a fairly good end-reaction, although affected somewhat by free carbonic and hydrosulphuric acids. In normal sulphites half of the base can be estimated with standard acid, as has been already shown by Giles and Shearer. Of the phosphates, the di-acid one (NaH_2PO_4) is indicated as neutral, and in this and the case of the sulphites is seen the dissimilar characters of cochineal and phenolphthalein or turmeric. The former agrees with methyl-orange and lacmoid paper, in giving the same results with the substances mentioned, but yields in delicacy of end-reaction to the two latter indicators. In other respects, also, cochineal resembles methyl-orange and lacmoid, inasmuch as it is entirely useless in presence of organic acids.

The radical defect of cochineal when employed in alkalimetry is occasioned by the damaging influence of the presence of even small proportions of alumina or iron, which cause the pink colour, though modified to some extent, persistently to remain even after the addition of excess of acid.

In spite of its fine colour, the application of cochineal must necessarily be very limited, and when methyl-orange and lacmoid can be so easily obtained and possess such conspicuous advantages over it, this indicator must be included in the list of those which may be fairly described as unnecessary.

Dimethylamidoazobenzene.

This compound was proposed by Fischer and Philipp as a substitute for methyl-orange, and was stated by them to be superior to the latter in delicacy. Its natural colour and that produced by the addition of an acid are similar to methyl-orange, but it requires to be kept in alcoholic solution. The dimethylamidoazobenzene I employed was prepared by Prof. Lunge, to whom I am indebted for a specimen which I received more than a year ago, accompanied with a request to communicate my opinion of its merits. I found that it acted precisely like methyl-orange, in being unaffected by free carbonic, hydrosulphuric and boric acids; in indicating the same neutral point in the titration of various salts with acid, such as the sulphites and phosphates; and in being valueless as an indicator for organic acids. In common with methyl-orange, dimethylamidoazobenzene is unable to detect acidity in presence of nitrous acid or a nitrite, a peculiarity which, among all the indicators I have yet examined, belongs only to those two. It must be acknowledged, as has already been advocated by Lunge, that the end-reaction obtained with methyl-orange is not inferior, but if anything superior, to that of Fischer and Philipp's indicator. In its own department, methyl-orange remains unrivalled as a solution indicator; and its best substitute, when darkness of colour or other circumstances renders this necessary, is lacmoid paper.

Congo-Red.

This compound is soluble in water with production of a solution of blood-red colour, which is changed to blue by the addition of acids. Red paper can be prepared by passing slips of filtering paper through the solution, and drying. Owing to the blue compound being nearly insoluble in water, the blue paper cannot be made by simply adding acid to the red solution, but must be obtained by immersing the dried red paper in dilute acid. Congo-red has been of late highly eulogised as a very delicate test for free acids, and since completing my experiments, I have noticed that it has been directly recommended as an indicator in alkalimetry, with special application to the titration of aniline.

The same ground was gone over as with turmeric and the other indicators, but I do not propose to go into great detail, as the results were discouraging. It was found that in titrating a cold solution of the carbonate or sulphide of an alkali metal with acid, the liberated carbonic or hydrosulphuric acid somewhat affected the colour, slightly purpling the red. In a boiling solution a considerable excess of acid did not effect any decided change in colour. Even in a cold solution containing 2grms. of hydrate of sodium in 100cc. of water, where traces only of carbonate were present, the effect of a drop in excess of normal sulphuric acid was simply to render the bright red of a dirty brownish-red colour, which is a very undesirable end-reaction. On further addition the solution became purple, and the full blue colour did not appear after the addition of 1cc. of the acid in excess, an effect which was produced by 0·2cc. in pure water coloured with the same amount of Congo-red. This injurious effect was traced to the normal sulphate of sodium formed, and the same phenomenon was observed when normal acid was dropped into pure solutions of the sulphates, chlorides and nitrates of sodium, potassium and ammonium.

The Congo-red paper was found to be of little value, as a considerable excess of free acid was very slow in its action, and the change to blue was not at all decisive. The blue paper indicates more sharply, but shows a tendency to redden even when there is a trace of acid present with the normal alkaline salt, and the exact point at which neutrality was reached was thus rendered doubtful. Congo-red behaves like methyl-orange and lacmoid paper in showing bisulphites, diacid phosphates and bichromates to be practically neutral, and being altogether useless for organic acids. But at its best it lacks the sharpness characteristic of methyl-orange and lacmoid paper, and the only conclusion which can be arrived at is that Congo-red must be excluded from the list of generally useful indicators.

I have already noticed the fact that Congo-red has been much recommended as a very delicate indicator for free acids. A vague statement like this is of little use, as the possession of the property described is the primary claim of any substance to be regarded as an indicator. The information really required is a comparison of its power with that of other indicators. I formerly gave results, showing the amount of acid or alkali required to completely transform the colour of definite quantities of these substances. For each test I used 100cc. of pure water and 0·5cc. of the indicator solution, the strength of which was so arranged that each gave, as nearly as could be judged by the different tints, the same intensity of colour. The quantity of pure dry Congo-red was 0·5grm. per litre, and 0·5cc. of this solution required fully 1cc. of decinormal acid to change the colour entirely. To effect the same result litmus and methyl-orange required 0·5cc., and for lacmoid, reddened phenolphthalein and cochineal, only 0·1cc. of the acid were required. Instead of being one of the most delicate tests for acids these experiments exhibit Congo-red as the lowest in the scale as regards sensitiveness. Carrying inquiry further, it was found that in a mixture of 12 parts normal acetate of sodium and one part of glacial acetic acid, free acid could not be detected at all with Congo-red. This last fact reduces to an absurdity the unqualified statement we have been considering, and clearly proves that the ability of any indicator to detect free acid is wholly dependent on circumstances.

Congo-red has been recommended by Messrs. Williams and Watson Smith (*Jour. Soc. Chem. Ind.* v. 72—75) as a good indicator for the detection of free acid in alum; but I have not been so fortunate as to be satisfied with its capabilities in this respect. For the experiments, 1, 2, and 3 per cent. solutions of the finest Turkey-red alum, five times recrystallised, and a Congo-red solution, containing 0·5grm. of the dry substance per litre, were prepared. On testing 100cc. of these alum solutions, it was observed that the first two drops of the indicator solution added did not produce much colouration, and that 0·15cc. was the smallest practicable amount that could be employed. The colour thus developed showed distinctly purple when compared with the same amount of Congo-red in pure water. Now, this result disagrees with the opinions expressed by Messrs. Williams and Watson Smith, who agree in saying that pure alum gives no reaction with Congo-red, if the latter be dilute enough. However, going a step further, it was found that with the 1 per cent. solution of alum, an addition of 0·2cc. of $\frac{N}{5}$ sulphuric acid produced only an almost imperceptible darkening of the purple, and that a large excess of acid failed to bring out the expected full blue colour. The tints of the 2 and 3 per cent. solutions of alum were even more difficult to judge. In the face of these results, which are quite in keeping with those already described, I think we must accept the conclusion without the least hesitation, that congo red is incapable of detecting with anything approaching to a certainty 0·2 per cent., or even of giving a trustworthy indication of the presence of 0·5 per cent. of free sulphuric acid in alum. I have not yet had opportunity to examine this subject further than to observe that methyl-orange is superior to Congo-red, and that lacmoid is useless.

Classification of Indicators.

The definite difference shown by various indicators, and the similar results afforded by others, point to the conclusion that it might be possible to classify them according to their general characteristics. In the determination of pure hydrate of sodium, potassium, calcium, and barium, with standard hydrochloric and other strong mineral acids, all indicators act alike; but it is in the titration of a weak acid with a strong base that diversity of behaviour makes itself apparent. Take, for example, the neutralisation of sulphurous acid with caustic soda. Methyl-orange shows the acid sulphite ($NaHSO_3$) to be neutral, while phenolphthalein remains unaffected until the normal sulphite (Na_2SO_3) is produced. The end-reaction with litmus paper lies between these extremes, although nearer to the phenolphthalein result, but it is not sharply defined like the other two. These essential differences are also observed in the neutralisation of the normal carbonates, sulphides, phosphates, arsenates, and other salts, as well as the organic acids. Basing our classification on these and similar facts, we find that indicators naturally divide themselves into three groups, of which the typical and most valuable members are repectively methyl-orange, phenolphthalein, and litmus. The following table includes the ten indicators I have experimented upon, arranged according to the plan just explained:—

Methyl-orange Group.	Phenolphthalein Group.	Litmus Group.
Methyl-orange	Phenolphthalein	Litmus
Lacmoid	Turmeric	Rosolic Acid
Dimethylamidoazobenzene	—	Phenacetolin
Cochineal	—	—
Congo Red	—	—

The members of the methyl-orange group may be described as those which are most susceptible to the action of alkalis; phenolphthalein, and turmeric, as those on which acids have the predominating influence; while the litmus group may be said to oscillate to some extent between these extremes, but more closely approximating to the second than to the first series. These distinctions must not be confounded with the delicacy of end-reaction, which is a totally different matter. When this arrangement of indicators is considered, it will appear that a solution might at the same time be alkaline, acid, and neutral, according to the indicator employed. An apt illustration of this fact may be remarked in saliva, which is on an average neutral to litmus paper, although it may be slightly acid or alkaline in certain circumstances, but is always strongly alkaline to lacmoid or Congo-red, and acid to turmeric paper. Fresh milk is another apposite example of a naturally occurring liquid which acts like saliva in the instances referred to.

The rules of classification here adopted are, like all general rules, liable to exceptions. Besides what may be called the anticipated similarity of behaviour of indicators belonging to different groups, as in these cases already alluded to, certain circumstances may arise in which this likeness unexpectedly manifests itself. This is well brought out by rosolic acid giving a sharp end-reaction in the titration of sulphurous acid with caustic alkali, and at the same time indicating normal sulphite as the neutral compound. In this exceptional case rosolic acid belongs strictly to the phenolphthalein group, while litmus and phenacetolin adhere to the general rule.

Purity of Indicators.

Reference has been occasionally made in chemical journals to the inefficiency of impure indicators, and methods suggested by which to test the purity of certain of these substances. It may be laid down as a fixed rule that litmus and turmeric should never be prepared by simply dissolving the commercial articles in water or alcohol, but should be previously purified according to the directions in Sutton's "Volumetric Analysis." With regard to methyl-orange, phenolphthalein, lacmoid, etc., it serves little purpose to determine whether they are of absolute chemical purity. All that is necessary is to observe whether their behaviour conforms to the descriptions given in this and former papers, and which have been confirmed by Lunge, Sutton, and other observers. It would thus appear that the most rational method of testing indicators is to apply them in several crucial tests, such as the titration of carbonate, sulphide, sulphite, phosphate, and borate of sodium, and acetic and citric acids. Not only must the delicacy or otherwise of the end-reaction be attended to, but also the percentage of alkali or acid obtained in these compounds. In all tests the temperature of the titrated solution should be taken into account, as, for example, the sulphite and mono-acid phosphate of sodium or potassium show more alkalinity to phenolphthalein in hot than in cold solutions, and in the latter case only is the end-reaction definite.

SELECT INDICATORS.

Although it is desirable to be acquainted with the properties of many indicators, yet it is useful to make a judicious choice of those which cannot be dispensed with in volumetric analysis. Of the ten indicators which we have been considering, the three representative ones are of primary importance. So far as the results of my experiments show, all the good and serviceable qualities required of indicators are held in comparatively greater perfection by methyl-orange, phenolphthalein, and litmus, than by the other seven. The only exception to this is in the neutralisation of sulphurous acid to normal sulphite of ammonium by the aid of rosolic acid, for which purpose all the remaining indicators are valueless. Litmus is the only one of those selected from which satisfactory papers can be prepared, and the advantage of having these as well as solution cannot be doubted. In nearly every particular, lacmoid paper, blue and red, is an excellent substitute for methyl-orange, and may be employed in coloured solutions, where the last-named indicator would be useless. The solution, however, is not so good, as it is slightly affected by weak acids, such as carbonic and boric, but the papers I find to be quite as effective as methyl-orange in these and similar cases. Turmeric papers, yellow and red brown, may be used in place of phenolphthalein, chiefly in the titration of weak organic acids; but there are many circumstances, as already pointed out, in which it is inadmissible. Provided with methyl-orange, phenolphthalein, and litmus, and with the addition of lacmoid and turmeric papers as valuable adjuncts, a chemist is now in a position, by simple means, to solve problems which were formerly incapable of solution.

This subject of indicators is an entirely new one, and although some interesting and useful facts have been discovered, infinitely more remains to be done in the way of developing the knowledge of those indicators already partially studied, and in the examination of others whose properties have not yet been investigated, or have only received the most superficial attention.

In the following table is given an epitome of the results obtained with indicators, and on which several processes have been based. The figures refer to the number of atoms of hydrogen displaced by the monatomic metals—sodium or potassium, when presented to the acid in the form of hydrate. From these results the composition of the salt produced will be easily inferred. When a blank is left, it is meant that the end-reaction is obscure, and not to be depended upon.

TABLE SHOWING THE BASICITY OF ACIDS WITH DIFFERENT INDICATORS, WHEN TITRATED WITH CAUSTIC POTASH OR SODA:—

ACIDS.	METHYL-ORANGE.	PHENOL-PHTHALEIN.		LITMUS.	
	Cold.	Cold.	Boiling.	Cold.	Boiling.
Sulphuric H_2SO_4	2	2	2	2	2
Hydrochloric HCl....	1	1	1	1	1
Nitric HNO_3..........	1	1	1	1	1
Thiosulphuric $H_2S_2O_3$	2	2	2	2	2
Carbonic H_2CO_3......	0	1 (dilute)	0	—	0
Sulphurous H_2SO_3 ..	1	2	—	—	—
Hydrosulphuric H_2S	0	1 (dilute)	0	—	0
Phosphoric H_3PO_4....	1	2	—	—	—
Arsenic H_3AsO_4......	1	2	—	—	—
Arsenious $HAsO_2$ ...	0	—	—	0	0
Nitrous HNO_2	indicator destroyed	1	—	1	—
Silicic H_4SiO_4	0	—	—	0	0
Boric H_3BO_3..........	0	—	—	—	—
Chromic H_2CrO_4	1	2	2	—	—
Oxalic $H_2C_2O_4$........	—	2	2	2	2
Acetic $HC_2H_3O_2$......	—	1	—	1 (nearly)	—
Butyric $HC_4H_7O_2$	—	1	—	1 (do.)	—
Succinic $H_2C_4H_4O_4$ ..	—	2	—	2 (do.	—
Lactic $HC_3H_5O_3$......	—	1	—	1	—
Tartaric $H_2C_4H_4O_6$ ..	—	2	—	2	—
Citric $H_3C_6H_5O_7$	—	3	—	—	—

Notes to Table.—(1.) The statements in the above table apply equally well to the titration of the various acids with ammonia, except in all cases where phenolphthalein is concerned, and when boiling solutions are employed. (2.) The hydrates of barium and calcium also give similar results with these acids, except in some cases where insoluble compounds are produced. Thus, carbonic acid is dibasic when titrated with barium hydrate with phenolphthalein as indicator. (3.) *Lacmoid paper* can be depended upon to act in every respect like methyl-orange, except that it is not affected by nitrous acid. (4.) *Turmeric paper* behaves like phenolphthalein with sulphuric, hydrochloric, nitric, thiosulphuric, nitrous, and the organic acids.

In the table below are brought together a few compounds whose action towards indicators could

TABLE OF COMPOUNDS NEUTRAL TO VARIOUS INDICATORS.

METHYL-ORANGE OR LACMOID PAPER.	PHENOLPHTHALEIN OR TURMERIC PAPER.	LITMUS SOLUTION OR PAPER.
Ferrous Sulphate	—	—
Ferrous Chloride	—	—
Copper Sulphate ($CuSO_4$)	—	—
Copper Chloride ($CuCl_2$)	—	—
Zinc Sulphate	—	—
Phenol	—	Phenol
Urea	Urea	Urea
Gelatin	Gelatin	Gelatin

not be deduced from the previous table. Those substances whose names are given are neutral to the indicator under which they are arranged, and those which are mentioned under methyl-orange and lacmoid, but otherwise unnoticed, are more or less acid to phenolphthalein, turmeric, and litmus.

DISCUSSION.

Mr. **Ellis** rose to ask Mr. Thomson if he had found a good indicator for boracic acid, as he had worked with several of the indicators mentioned without obtaining satisfactory results?

Dr. **Mills** ventured to suggest, as regarded the acidity of alum, the desirability of making an experiment with the addition of common salt; taking pure alum solution, and then making up similar solutions containing greater quantities of acid. He believed that common salt would cause a sharper response to the indicator.

Mr. **Stanford** thought all chemists would be indebted to Mr. Thomson for the remarkable way in which he had put the relative powers of the various indicators. There was one point, however, upon which he sought a little further information—namely, with regard to the indicator lacmoid. He gathered from Mr. Thomson's remarks that the paper and the solution differed considerably in their action, and he would like, therefore, to know more about that difference, and also how the substance was usually prepared for use in analysis.

Mr. **Thomson**, in reply, said that with regard to Mr. Ellis's question, there was no indicator, so far as he knew, that could be used in the estimation of boric acid. To methyl-orange boric acid was neutral, but after trying all the other indicators he had found none of them gave a good end-reaction or reliable results. Poirrier's blue had been said to give good results with that acid, but he had seen its value in other respects contradicted by other chemists, and was afraid that it would not be up to the mark; in the meantime there was no indicator known for that purpose. Professor Mills' idea might be a correct one, although it would require to be tested by experiment. With regard to Mr. Stanford's question about lacmoid, he was unable to tell why there should be a difference between the paper and the solution. In the case of the neutralisation of carbonate of sodium, with the solution present it was found that the liberated carbonic acid had a slight purpling effect on the blue. If the paper was inserted in such a solution the blue was sometimes faintly reddened, but when removed from the liquid was found to come back again. With mono-acid sodium phosphates, the purple came on long before the end of the reaction was reached, but the paper showed the exact point at which the diacid salt was formed. The action of the paper was slow, probably because the blue being very insoluble, adhered strongly to the fibre of the paper, and could not thus be quickly changed in colour. It had to be kept immersed for a minute or so. Only a small slip of paper was used. The method of preparing lacmoid was given by Traub and Hock as follows: 100 parts of resorcin, 5 parts sodium nitrite, and 5 parts water are heated at a temperature not exceeding 120° C. until ammonia ceased to be evolved. This mass is dissolved in water, and forms an intense blue solution. By adding hydrochloric acid the lacmoid is precipitated. It is only necessary then to collect it, wash with water, and dissolve in alcohol of about fifty per cent. strength.

THE MANUFACTURE OF GAS FROM PARAFFIN OIL, WITH A DESCRIPTION OF A SIMPLE FORM OF APPARATUS SUITABLE FOR THE DISTILLATION OF OILS INTO GAS.

BY W. IVISON MACADAM, F.I.C., F.C.S.,

Professor of Chemistry, New Veterinary College, Edinburgh.

The subject that I have the honour of laying before you this evening is one to which, from time to time, we have been called upon to give professional attention. The facts thus obtained have been added to by a series of experiments undertaken during the present session, and the results of which are now laid before the Section, in the hope that they may aid the general fund of information which will require, sooner or later, to be much extended.

Various grades of oil have been destructively distilled, the temperature being carefully regulated according to the class of oil experimented with.

The first series of trials were made with—

1. *Crude Paraffin Oil* as obtained from the shale retorts and without any further treatment. The sample had a specific gravity of 850 (water 1000); a flashing point of 92° F.; and a firing point of 106° F.

2. "*Green Oil*," which is obtained from the crude shale oil by redistilling. The sample had also had the lighter oils (naphthas) removed by fractional distillation: specific gravity, 884; flashing point, 165° F.; and firing point, 193° F.

3. "*Twice-run Oil.*"—This oil is obtained from the crude oil by distilling (the naphthas not being removed), treating with soda and vitriol, and redistilling without fractionating. The sample had a specific gravity of 802·30; a flashing point of 67° F.; and a firing point of 74° F.

4. "*Burning Oil*" obtained from the previous sample by re-treating with soda and vitriol, and distilling in fractions. The sample had a specific gravity of 805.

5. "*Crystal Oil*" obtained from the burning oil by re-treatment with strong oil of vitriol: specific gravity, 798; flashing point, 107° F.; firing point, 123° F.

6. "*Petroleum.*"—This was a sample of ordinary American oil; the specific gravity, 799; flashing point, 84° F.; firing point, 99° F.

7. *Rectified Coal Oil.*—Specific gravity, 844; flashing point, 212° F.; firing point, 230° F. This, and the preceding sample, were distilled, so as to compare the results with those obtained from the ordinary mineral oils.

8. "*No 2 Burning Oil*" obtained by breaking or "cracking" heavier oils: specific gravity, 830; flashing point, 230° F.; firing point, 250° F.

9. "*Intermediate*" *Oil.*—Specific gravity, 846; flashing point, 254° F.; firing point, 280° F.

10. "*Intermediate*" *Oil.*—Specific gravity, 868; flashing point, 203° F.; firing point, 262° F.

11. "*Intermediate*" *Oil.*—Specific gravity, 871; flashing point, 231° F.; firing point, 286° F.

(The above three samples of oil were "*unfinished.*")

12. "*Blue*" *or Lubricating Oil* from which the solid scale had been removed, the oil receiving no further treatment: specific gravity, 878; flashing point, 163° F.; firing point, 268° F.

13. "*Blue*" *Oil.*—Specific gravity, 868; flashing point, 270° F.; firing point, 335° F. This sample was specially fractionated from light oils.

14. *Light Lubricating Oil* freed from scale, treated and redistilled: specific gravity, 873; flashing point, 270° F.; firing point above 300° F.

15. *Heavy Lubricating Oils* freed from scale, treated and redistilled: specific gravity, 250; flashing and firing points above 300° F.

16. "*Gas Oil*" obtained from the acid paraffin tar by distillation: specific gravity, 828; flashing point, 119° F.; firing point, 134° F.

The crude paraffin oil and "green" oil, as well as the "blue" oils, were run in Keith's or Pintsch's apparatus, the remaining tests being made with the Alexander and Paterson apparatus, which I shall describe more fully towards the close of my communication. The averages of all the results obtained from "blue" oils in Keith's and Pintsch's apparatus are given in separate columns.

The results are stated as follows:—

1. *Specific gravity* of the oil taken at 60° F., or calculated down to that temperature, compared with water as 1000.

2. *Weight of one gallon of the oil* calculated from the specific gravity.

3. *The number of gallons of oil in one ton* by weight.

4. The temperature at which the oil *gave off inflammable vapours* — "flashing point."

5. The temperature at which the oil became *permanent inflamed* — "firing point."

6. The *amount* of gas in cubic feet obtained from *one gallon* of the oils.

7. The *proportion* of gas obtained from *one ton* of the oil.

8. The *candle power* of the gas, as determined by Bunsen's photometer. The gas was burned during the testings at the rate of 0·75 cubic foot per hour, and consumed through a No. 0000 burner specially constructed for me through the kindness of Mr. George Bray, of Leeds. The results were afterwards calculated to the value of 5 cubic feet of gas, and are stated in standard sperm candles, each consuming 120 grains of sperm per hour.

9. *Illuminating value of one cubic foot* of the gas in grains of sperm.

10. *Illuminating value* of the gas from one gallon of oil in lbs. of sperm.

11. *Illuminating value* of the gas obtained from one ton of the oil, in lbs. of sperm.

12. The proportion of *hydrocarbons* absorbed by bromine.

Summary of Results.—The results of the various tests as given in the accompanying tables show that—

1. *The Crude Oil* gave from one gallon 98¾ cubic feet of gas, which is equivalent to 26,026 cubic feet per ton of oil. The candle power was equal to 50¼ standard candles, or to 4494lb. of sperm per ton of oil. Some difficulty is experienced in working this class of oil, as it requires to be liquefied before being passed into the retort. The comparatively large proportion of carbon separated during the distillation renders it impossible to use the Alexander and Paterson apparatus, or any similar work in which the oil requires to flow through tubes. The gas is much more impure than is the case where the semi-refined or refined oils have been distilled, and it is a question whether these very crude oils will prove to be so economical as the purer varieties, and more especially the "intermediate" oils.

2. "*Green*" *Oil* gave from one gallon 102⅓ cubic feet of a gas of 53¼ candle power, and a total value in lighting power per ton equal to 4741lb. of sperm.

3. "*Twice-run Oil*" yielded 106 cubic feet of gas per gallon. The quality was equal to 70 candles, and to 7105lb. of sperm per ton. The total amount of gas obtained was 29,605 cubic feet per ton, and is the largest proportion of gas we have yet obtained from any oil.

4. "*Burning Oil*" also gives a high result, being equal to a total production of 27,484 cubic feet of a gas of 63 candle power, and of a total illuminating value of 5950lb. of sperm per ton.

5. "*Crystal Oil*" gave 29,928 cubic feet of a 54 candle gas, and a total illuminating value equal to 5538lb. of sperm per ton of oil.

6. *American* "*Petroleum.*"—This oil was most carefully tested time after time, but the quantity of gas obtained was always much below that of the ordinary "paraffins." Whilst this was the case, the illuminating value was above that of the home oils, being equal to 66 candles, or a total value per ton of oil of 5506lb. of sperm. The average quantity of gas from the ton of oil was 21,110 cubic feet. The difficulty of distillation may be due to the very different chemical composition of the American oil, and the lower temperature required to break up the paraffins which predominate in the American material as compared with the home oils, which contain an excess of the olefines.

7. *Rectified Coal Oil.*—The total amount of gas from this substance was 25,282 cubic feet per ton, and the illuminating power equal to 42½ candles. The total illuminating value was equal to 3689lb. of sperm per ton of oil.

8. *No. 2 Burning Oil* gave 27,171 feet of a 49¾ candle gas, and a total illuminating value equal to 4635lb. of sperm.

9. *Intermediate (Unfinished) Oil* of 846 gravity gave of gas 24,922 cubic feet. The illuminating power was equal to 60 candles, and the total value to 5139lb. of sperm.

10. *Intermediate (Unfinished) Oil* of 868 gravity yielded 24,383 cubic feet of a gas of 56¼ candle power. The illuminating value of the ton was equal to 4702lb. of sperm.

11. *Intermediate (Unfinished) Oil* (871 gravity) gave 24,396 cubic feet of gas. The candle power was 57½, and the total light-giving value equal to 4822lb. of sperm.

12. "*Blue*" *Oil* of 878 gravity yielded 32,492 cubic feet of gas, the power of which for illuminating purposes was equal to 54¼ candles, and to a total illuminating value of 6047lb. of sperm.

13. *868 Blue Oil* gave per ton 33,529 cubic feet of gas, the candle power of which was 54¾, and the total illuminating value 6295lb. of sperm.

14. *Light Lubricating Oil.*—This oil, when distilled, yielded 26,273 cubic feet of a gas of 61⅓ candle power, the total value being equal to 5521½lb. of sperm per ton of the oil.

15. *Heavy Lubricating Oil* yielded 23,653 cubic feet of a gas which was of 57¼ candle power, the total illuminating value per ton being equivalent to the consumption of 4643lb. of sperm candles.

16. "*Gas Oil*" from acid tar gave 25,963 cubic feet of a gas of 43⅓ candle power, and was equal in value to 3854lb. of sperm candles.

Whilst it is possible to employ all of those varieties of oil, yet it is principally those qualities *intermediate* between the burning and lubricating oils that we consider especially interesting. The somewhat large proportion of those oils which are obtained in some works, and the extremely limited demand in the market, has caused much concern to the paraffin oil companies. Various endeavours have been made to limit or altogether do away with the production of these oils, but with limited success. The manufacture of gas seems to me to be one solution of the difficulty, and the large proportion of material obtained, as well as the high candle power, is much in favour of the process. It is doubtful if the retorting of shale for the single purpose of manufacturing an oil for gas-making would prove commercially successful, as there is always a heavy loss of total illuminating value during the crude distillation, as well as in the purifying processes. As illustrating this point, a cannel coal was distilled for gas with the result that 12,208 cubic feet were obtained of 35·62 candle power. The total light-giving value was equal to 1490·91lb. of sperm. When distilled for oil the same coal gave 63·72 gallons of crude material per ton distilled, and taking the gas-making value at 100 cubic feet per gallon, we have 6372 cubic feet of gas per ton of coal. Against this, however, the candle power was raised to 50, but the total illuminating value was only equal to 1092·34lb. of sperm per ton of coal. Further, when the crude oil was rectified the following products were obtained: Naphtha, 1·44 gallons; burning intermediate oils, 22·39 gallons; lubricating oil, 14·87 gallons; and scale, 6·01 gallons per ton of shale; the total of the refined products being equal to 44·71 gallons, with an average specific gravity calculated at 836. Taking the possible gas produced at 100ft. per gallon of oil, we have a total of 4471 cubic feet of gas per ton of coal. The illuminating value of the gas would be about 55 candles, or a total illuminating value per ton of coal of 843lb. of sperm, in opposition to 1491lb. when the coal was distilled into gas direct. The objection to the above line of argument undoubtedly lies in the fact that a coal of the quality referred to would never be retorted for oil, and that the proper line would be to consider the relative values of shale and the products obtained therefrom. Here we have a new factor to take into account in the very large proportions of ash, and the consequent heavy carriage payable on useless material. I do not propose to enter into such a calculation, as I do not presume that it could be seriously thought possible to transmit shale for gas making purposes to any great distance, or that it will be to any great extent distilled for gas direct. The quantity of ash alone would, in many cases, render it impossible for a gas company to use a material which would leave so large an amount of substance—perfectly useless—to be removed from the works at considerable cost. Again, I say that it is in the use of the less valuable "intermediate" oils that the true province of gas oils will be found.

One other comparison may be given. It has been proved that when paraffin oil is consumed

in lamps *as oil*, there is no difficulty in obtaining from the material a light equal to 27lb. of sperm per gallon of oil. Now the total value of one gallon of oil after distillation into gas is only 21·65lb., and there is therefore a loss equal to nearly 5·5lb. of sperm per gallon of oil. Doubtless, this may be improved on, but in the meantime we are again driven to the use of the cheaper "intermediate" oils—bodies too heavy for consumption in lamps, and too thin in "body" for lubricating purposes.

In conclusion, I should desire to describe the apparatus employed to obtain the foregoing results. It is the invention of Mr. Paterson, of Messrs. Alexander & Paterson, gasfitters, of Kirkintilloch. The retort is of cast-iron, and has the oil introduced into it by means of pipes carried through the retorts from the front to near the back. During its passage through these pipes the oil becomes vapourised, and is broken up by its after-contact with the heated sides of the retort in its return passage to the outlet, which is placed in the front part of the apparatus. The gas is afterwards cooled in upright pipes, and, if necessary, may be passed through the ordinary dry purifiers, and stored for use. The permanency of the gas has been frequently tested by myself, and proved to be excellent, and quite equal to any ordinary coal-gas. One great advantage the apparatus possesses is its extreme simplicity and non-liability to get out of order. Once started, it works away, and with an occasional glance at the heating apparatus, may be continued without trouble for any desired period. My own gas-works will manufacture about 80 cubic feet of gas per hour; but, of course, the retorts may be greatly enlarged or increased in number, according to the consumption and production required.

DISCUSSION.

Dr. **Wallace** asked whether Mr. Macadam had tried ordinary crude oil from blast-furnace tar, without any kind of rectification. He had made a trial of this himself, but did not get very promising results. In the first place, it gave a pretty large amount of tar in the condenser—somewhere about one-third of the oil itself; and there was, moreover, a tendency to choke up the pipes, and also to deposit carbon in the retorts. If this oil could be used for the manufacture of gas—being the cheapest oil in the market—it would be of great consequence, because it might be used in conjunction with splint and common coals for the manufacture of gas of medium illuminating power, say 22 to 26 candles. In referring to rectified coal oil, Mr. Macadam had not particularly mentioned what kind of coal oil this was—whether from blast furnace, or made in coking ovens. The whole subject was one of great importance, and was daily becoming of greater consequence, because our fields of cannel coal, especially of better class, were being rapidly wrought out; and some gas companies and corporations had thought it necessary to look before them, and even to reduce the quality of their gas, in anticipation of the difficulty they would experience by-and-bye of obtaining supplies of first, or even second-class coal. It was, therefore, a subject fraught with commercial interest, and the Section were indebted to Mr. Macadam for the able manner in which he had brought it before them.

Mr. **Foulis** was not prepared to say much on this subject, as it was one he was just beginning to study. He would like to know, however, the advantages which this new apparatus possessed over the other forms of apparatus, such as Pintsch's. He confessed that, at first sight, he did not like these small tubes, which, under Mr. Macadam's care, might not choke up; although, in the ordinary course of gas manufacture, he was afraid this would occur. There was no doubt whatever that the interior of the retort would become, in a very short time, coated with carbon. The whole process was one of decomposition of the oil; the carbon resulting from this decomposition would be deposited in the retort, and more especially deposited on the roof of the retort. It appeared to him, therefore, that these tubes, being fixtures, would render it very difficult to cleanse the retort out. These were, of course, points on which he might be mistaken. There was a further point to which he would refer, and perhaps Mr. Macadam's attention had been directed to it—namely, whether or not there was any advantage in using, in conjunction with the oil, a jet of steam, in order to carry forward into a more permanent form some of the oils that would otherwise be condensed from the gas. There was a very simple method of gas making adopted in America, which had this advantage, that it could be applied to the ordinary retort, and it could be removed at once, if so desired. It consists of a pipe closed in the front end attached to the door, and carried back to the near end of the retort, into which another pipe is inserted, closed at the inner end. The oil is blown by a jet of steam into this inner pipe, and is there converted into vapour, and, passing from this, it comes in contact with the retort, and the oil is decomposed. The great advantage of this was that the apparatus might be removed at once, the retort cleaned out or charged with coal. With regard to the permanency of the gas, it was well known that gas, even when compressed, if allowed to remain still, did not lose a very great deal of its illuminating power; but whether this gas would stand the test of passing through pipes in cold weather without losing illuminating power, was a point on which he would be glad if Mr. Macadam would give some information.

Professor **Mills** asked how long a retort of this description could be run without being stopped for cleaning out, and, further, the cost of making the gas? The temperature required for a retort of this kind was exceedingly high, as would be seen from the formation of naphthalene. The amount of coal used for the destructive distillation of the oil was certainly very high, and it would be interesting to know the amount of coal used, for, say 30,000 feet of this gas. As regarded the composition of the gas, he was glad to hear that Mr. Macadam had promised to give some analyses of these destructive distillations. If the gas could be dissected out, and the non-luminous constituents set recorded on one side, and the luminous constituents on the other, they would then be in a position to make a better comparison with coal gas than was the case at present.

Mr. W. R. W. **Smith** said he was greatly struck some five or six years ago, in passing through Germany, to find that a commercial friend of his had all his mill lighted with gas made from oil by means of a small apparatus about twenty feet in length. He was so much astonished some time ago at the low price of oil from the blast furnace, that he procured a sample and sent it to his friend. This led to a demand for one cask, then five casks, and his friend had now laid in his winter stock of this oil, with which he lighted his mill, but of which Mr. Macadam could make very little. It was evident, therefore, that here in Glasgow they were groping after a thing which was being carried out elsewhere, and he would be glad to place at Mr. Macadam's disposal the drawings of this apparatus.

Mr. **Macadam**, replying to Dr. Wallace, said he had not as yet got satisfactory results from crude blast-furnace tar. He did not think that the "Paterson" apparatus would give good results with such oils. The figures obtained had been as yet of no practical value, and had therefore not been included in the present communication. The rectified coal oil was obtained from the regular coke ovens. Dealing with Mr. Foulis's remarks, there was no doubt that the tubes (small or big) would at first sight appear to a practical man to be a drawback to the apparatus; at the same time he had worked with it for some months without any choking of the tubes. This was probably the best answer to the question. He attempted some days ago to retort colza oil, but partly from the high viscosity and the comparatively large amount of carbon in the oil, he had not obtained good results. He pointed out, however, that this was an apparatus for "intermediate" and "burning" oils, and not for crude oil or oils of great viscosity. As a matter of fact, the apparatus had been in the hands of practical men for months, and had been found to work with perfect ease. The workmen who were in charge were not skilled or specially-trained men, but in all cases the apparatus had given satisfaction. The tubes were scarcely fixtures. In the retort which he had used for coal-testing and oil-testing indiscriminately, the tubes were attached to the door of the retort, and could be removed with the door, so that no trouble was experienced in regard to that point. The quantity of carbon deposited was not so great as might be expected, and it was very seldom that the apparatus required to be cleaned out, but when such became necessary the door and tubes were easily removed. In the larger apparatus of the same makers the door was cast in two parts. To the upper part the tubes were attached. The lower portions of the door could be removed separately, and the retort cleaned out without interfering with the tubes. If heavy oils were worked, it might be necessary to clean the retort more frequently out. With the class of oils referred to (burning and intermediate) very little cleaning would be required. Touching on the use of a jet of steam, he did not include that method of working in this paper, although he had made experiments in that direction, and desired, if permitted, to lay the results before the Section at a future meeting. The apparatus, to yield good results with steam, would require to be somewhat changed, so as to allow of a longer period of contact between the oil and steam and the sides of the retort. In regard to the question of permanency, the gas had not only been retained for long periods over water, but had also been passed through lead pipes 100 feet in length, which was a very severe test. The temperature was below freezing point, and the gas was found to be, in proportion to its illuminating value, as permanent as ordinary Edinburgh gas. The tar contained a large proportion of naphthalene, but the proportion of tar was small. He could not say that there was a large proportion of naphthalene present in the gas. During the distillation of the tar from the Alexander and Paterson apparatus he got a considerable proportion of naphthalene. He was sorry he could not, on the moment, give the cost of 30,000 feet of gas. Of course much depended on the quality of oil to be distilled. From "intermediate" oils about 24,000 cubic feet of gas could be obtained from the ton of oil. Such oils could be bought at present at about 1½d. per gallon, which was equal to about 30s. per ton. The gas was of about 60 candle power, so that, roughly speaking, the ton of oil gave gas equal in illuminating value to about 72,000 cubic feet of 20 candle gas. The retorting was certainly not so costly as with coal, for it must be kept in mind that whilst the temperature of the retort was much the same as with coals, yet a great saving must take place in the cost of labour for charging and emptying of retorts, which operations practically ceased to exist when oil was used for gas making. The actual amount of coal should also be less for a given amount of heat, as there was no ash to raise in temperature, as was the case with coals. He was at present engaged in analysing the various gases, but as these results were of little practical interest they were not included in the present communication, excepting only the amount of absorption due to bromine, which was given in the tables, and which might be averaged at from 30 to 35 per cent. of the gas. American petroleum had proved difficult to distil into permanent gas. The proportion which had been obtained from it was less than with the home oils. No doubt this was due to the difference in the chemical composition of the body, there being in the petroleum more of the true paraffin and less of the olefine group, whilst in the home oils the olefines predominated. American petroleum required a distinctly lower temperature.

No. of Revolutions.	Time.	Sperm Oil.		Caspian Oils.				Spindle Oil (partly Sperm and partly Mineral Lubricating).	
			Increase.		Increase.		Increase.		Increase.

Mr. Macadam then exhibited Bailey's oil tester, and gave a brief description of it. The apparatus, he said, was largely employed to test the relative lubricating value of oils. The apparatus was constructed in such a way as to place the oils being tested in as nearly as possible the same condition as they would be in actual work. The machine was driven at 2000 revolutions per minute, and the temperature of the bearing-block was noted at so many different revolutions. The usual number of revolutions stated in the certificate of testing were 5000, 10,000, 15,000, and 25,000, and the temperature was noted at each of those points.

The above table gives the results of tests made with the apparatus—the temperature at starting being in all cases 60° F.

All tests for viscosity and lubricating value were comparative, but this apparatus gave constant and reliable relative results. After the above tests were made, if it was desired to subject the oils to a more severe, and at the same time practical, test, then the apparatus was allowed to remain for 24 hours, after which it was re-started without being further oiled or cleaned, when a set of results were obtained from which the liability of the oil to oxidise or "gum" could be determined.

ON LABORATORY FITTINGS.

BY JOHN GIBSON, PH.D.

About four years ago Professor Crum-Brown asked me to draw up detailed plans of fittings for the new chemical laboratories of the University of Edinburgh. In accordance with this request, I visited many of the principal laboratories in this country and on the Continent. I afterwards drew up plans of fittings which were approved of, in almost every detail, by Professor Crum-Brown and by the building committee.

In the following paper I have endeavoured to describe these fittings, which have been in use for some time back, in so far as they are novel or different from those generally to be found in the principal laboratories of the United Kingdom

I wish to acknowledge in the fullest manner my indebtedness to others for much invaluable suggestion. I desire especially to thank Sir Henry Roscoe, Professor Thorpe, Professor Fittig and Professor Pebal for the advice and help which I have received either directly or indirectly from them.

In the work of fitting up the new laboratories, Mr. Allan Clark, clerk of works to the University, has given constant and most valuable assistance.

There is no more fundamental requirement in a chemical laboratory, and, above all, in a laboratory designed for teaching purposes, than an efficient system of ventilation.

The problem which presents itself differs in one important respect from that presented by the ventilation of an ordinary hall or room, inasmuch as it is not sufficient merely to secure the removal of the impure air and its replacement by pure air of a suitable temperature. In a chemical laboratory it is generally desirable, and often absolutely necessary, to prevent the various fumes, which are evolved in the course of chemical work, from ever mixing with the bulk of the air in the laboratory. Although enormous improvements have been made in the construction and equipment of chemical laboratories in recent years, this problem still continues to offer special difficulties which have not, so far as I am aware, been overcome in a thoroughly satisfactory manner.

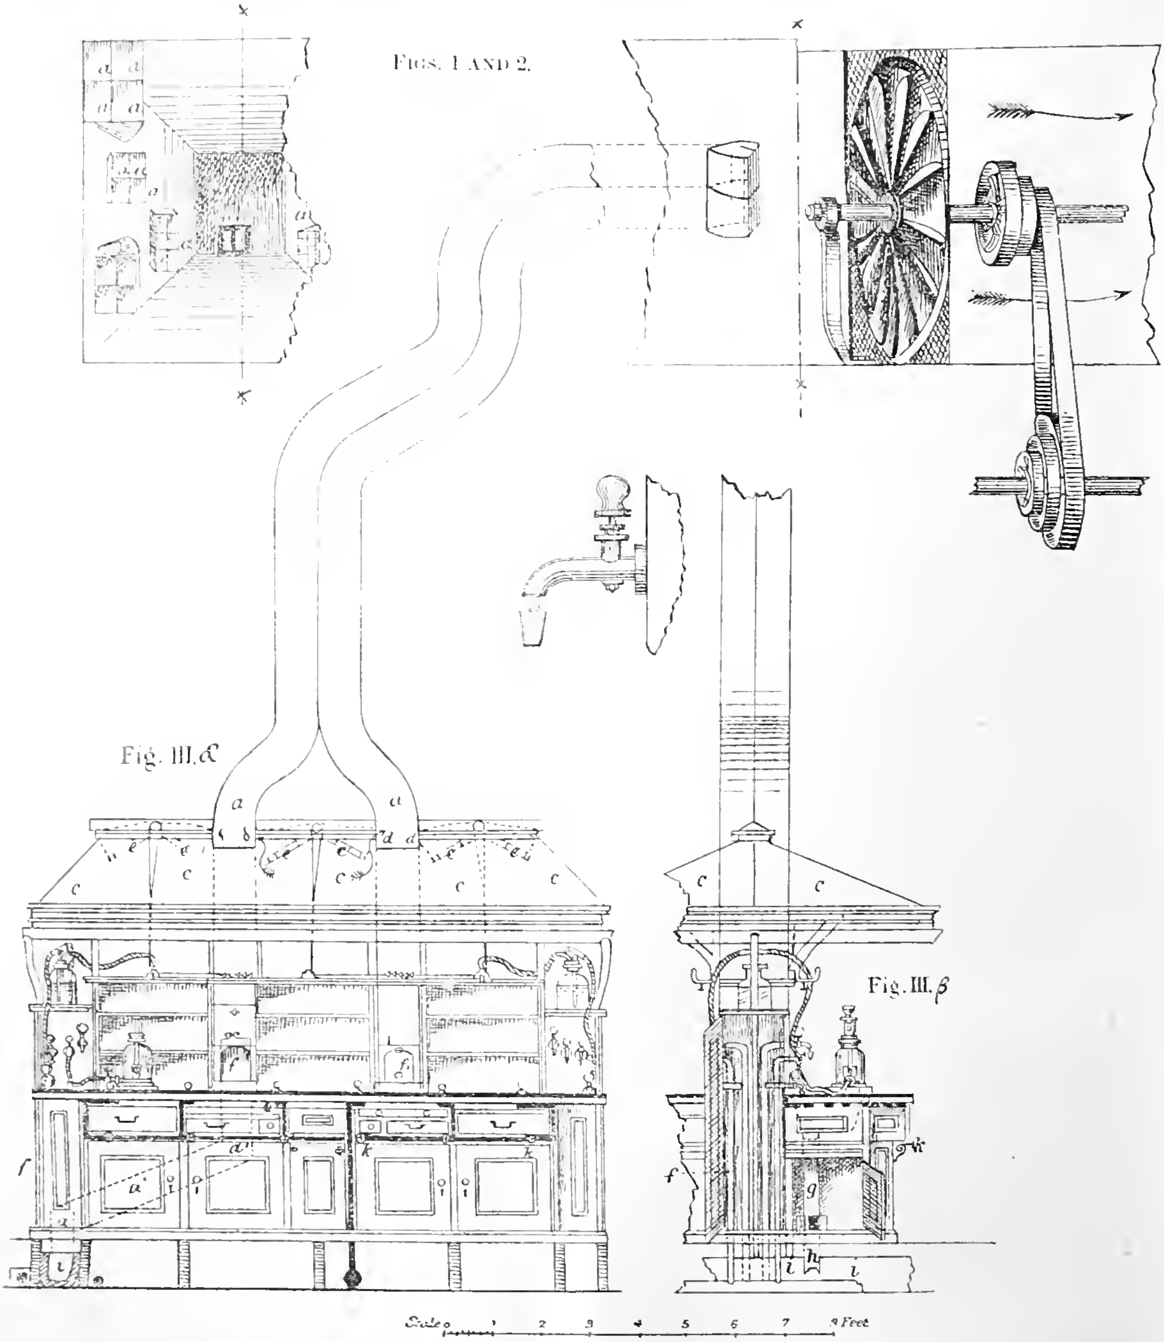
In most laboratories the usual means employed have been the erection of so-called draught cupboards for general use. A draught cupboard is most efficient as a means of preventing the admixture of the fumes evolved in it with the air in the laboratory, when *(cæteris paribus)* its dimensions are small; but a small draught cupboard is necessarily inconvenient, inasmuch as it cramps the operations of the worker, and is only available for small apparatus, or for a small portion of an extended arrangement of apparatus. In any case, a considerable number of them are necessary to meet even ordinary requirements. Larger draught cupboards, on the other hand, while more convenient in some respects, have their own peculiar disadvantages. They are always less efficient as a means of keeping the air of the laboratory pure, and when used, as they necessarily often are, by several workers at once, the greater freedom of operation is to a great extent lost; and further, when open vessels are being used, the fumes from one vessel are liable to affect the contents of the vessels near it.

A very simple and, at the same time efficient, plan, and one which has been adopted in some of the best of the Continental laboratories, is to connect each draught cupboard with a separate flue, in each of which a gas jet, or system of jets, is kept burning; the burners being either of the ordinary fish-tail kind or Bunsen burners. The jets should be situated at some distance above the bottom of the flue, an opening with a glass door opposite the jet or jets enabling one to see that the gas is burning properly, and to make any necessary repairs. Where the price of gas is low, this system presents many advantages. In the Owens College laboratory, for so long the best and most completely equipped in the United Kingdom, and in fact the only one which could be favourably compared with the great laboratories of the Continent, there is an excellent system of down draughts connected with and produced in one main central chimney. In Edinburgh it was originally intended to adopt a similar system, and the ordinary ventilation of the whole of the new University buildings is effected by a series of furnaces venting into an iron shaft which runs up the centre of a tall chimney stack, the draught flues leading into the annular space between the hot-iron shaft and the brickwork. The flues or down-shafts intended to carry off the fumes produced in the chemical laboratory lead into the central iron shaft.

From whatever cause, the draught supply, if I may use the term, available for the chemical laboratory proved altogether insufficient. It, therefore, became necessary to adopt a different system of fume extraction. This circumstance, although very annoying at the time, retarding, as it did, the opening of the new laboratories, is hardly to be regretted, for it has led to the adoption of a system in all probability far superior to anything which could have been economically attained on the above plan.

The draught is now produced by a Blackman air propeller four feet in diameter, and driven by a gas engine. The propeller or fan works at the open end of a wooden chamber (Figs. 1 and 2) 36ft. long, 5ft. across, and 5ft high. This chamber is situated immediately under the roof, and above the partition dividing the two main laboratories.

To this chamber up-shafts leading from the various places where a draught is required are conducted, and enter through the wooden sides of the chamber at different points on both sides, and also at the end opposite to the fan. The shafts, like the chamber, are constructed of deal boards, and in every case lead directly into the chamber, without intercommunication. Abrupt bends have been carefully avoided, and the end of each shaft leading into the chamber is in every case bent round, so that the mouth of the shaft faces the fan (Figs. 1 and 2, *a*, *a*). The velocity of the air drawn up is by these means rendered practically uniform in each of the shafts, and independent of the length of the shafts, or the position of their upper ends in the main chamber. The velocity of the current of air in each of them, depending as it does upon the rate at which the fan is driven, is perfectly under control, and is not appreciably affected by differences in the outside temperature, or by the direction and force of the wind. These are very great advantages which cannot, I believe, be attained by any non mechanical method. Whenever necessary, additional shafts can be run up in a day or two, and at small cost. The shafts are coated internally and externally with several layers of asbestos paint, and, in addition to this, are lined from their lower ends upwards to a height of about twenty feet with a coating of thin asbestos paper, which is caused to adhere to the painted wood by means of a solution of silicate of soda applied to both surfaces of the paper. This paper was subsequently washed with dilute hydrochloric acid, and finally, when dry, covered with a coat of asbestos paint. A piece of wood thus protected may be placed for any length of time over a powerful Argand burner, without giving the slightest sign of catching fire, provided, of course, that the flame does not come in contact with any unprotected wood. After a considerable time the wood is slowly and completely charred, the protecting coating remaining intact.



Figs. 1 and 2.

Fig. III. α

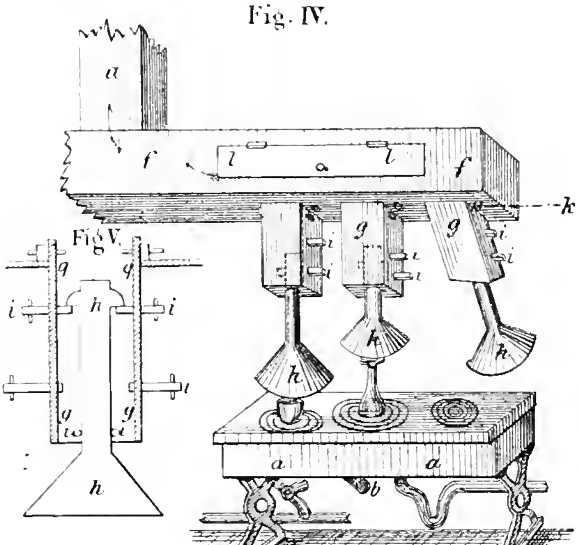
Fig. III. β

The great power of the draught thus produced has rendered it possible to dispense with draught cupboards almost entirely. The draught arrangements on the working tables are extremely simple, and may be readily understood by reference to Fig. 3. The draught shafts *a*, *a*, lead down through the ceiling of the laboratory and terminate at the top of the tables, at each working place. In each shaft there is an opening, *b*, *b*, Fig. 3, facing the worker, at a convenient height, and provided with a sliding shutter. If the worker wishes to perform any operation in which fumes are given off, he simply opens the shutter and places his apparatus opposite the opening, when the whole of the fumes are drawn up the shaft. It will be seen that the tables are further provided with glass hoods, *c*, *c*, Fig. 3. The object of these hoods is twofold. On the one hand they act as screens, preventing the fall of dust, and more especially of particles of lime or plaster from the roof, on to the tables and into the open vessels of the workers. On the other hand they collect and localise any fumes which are either accidentally or unavoidably produced at the several working tables. At the points *d*, *d*, Fig. 3, immediately below the top of the hood, there are two openings in each shaft, through which any fumes that may collect at the top of the hood are drawn away. Of course, if the air were allowed full and constant access to these upper openings, the lower draught tubes would be little or no use, as the draught through them would be almost entirely cut off. The wooden shutters, *e*, *e*, *e*, Fig. 3, swing on leather hinges, and can be opened at will to any desired extent. Being supported by cords in the manner shown in Fig. 3, they fall down by their own weight whenever the cords are slackened. In order to ensure their falling, the shutters are weighted with blocks of heavy hard wood, which have also made it possible to dispense with wheel pulleys, the cord being simply led through holes in the wood, as shown in the figure. Any arrangement of pulleys would be much more liable to get out of order, especially if made of metal, the use of which has been avoided in all the fittings as much as possible. In ordinary circumstances these shutters are left slightly open so as to permit of a slight current of air sufficient to carry off the small quantity of fumes, which are unavoidably produced during minor operations. Should, however, a large volume of fumes be on any occasion accidentally produced, the shutters can be instantly opened to the full extent, and the fumes, which collect under the hood of the table at which the accident has happened, are rapidly carried up the shaft without mixing with the atmosphere of the room generally, and thus leaving the workers at the other tables quite unaffected by them.

As a further means of keeping the air of the laboratory pure, communication is established between the draught shafts *a*, *a*, and the open gutters or waste pipes near the points where the sinks drain into them by means of the shafts, one of which, a^1 a^1, is indicated in broken lines in Fig. 3.

Another way of utilising the draught in connection with the steam-baths, is shown in Fig. 4. Each steam-bath consists simply of an iron box (*a*, *a*). The steam passes first through a long twisted coil of leaden pipe lying in the bottom of the box. The condensed water is run off at a point higher than the coil of pipe, so that the latter is completely immersed in the water. Every morning, before the laboratories are opened, steam is turned on by means of the tap *b*, and passing through the coil heats up the water, and is in part condensed in the coil, the remainder finally bubbling up through the water. As soon as the water is fairly boiling, the tap is nearly closed, so that while little or no steam escapes through the holes in the top of the bath, the whole arrangement is kept constantly at a temperature of very little below the boiling-point. If it is desired to use the bath, the tap is opened to any desired extent, the water then immediately begins to boil, and steam escapes from the holes at the top of the bath, and plays on the bottom of any vessel supported over them. This extremely convenient form of steam-bath was, I believe, first introduced into laboratories in Germany, by Dr. Hirzel, of Leipzig. The usual method of carrying off the fumes from such a steam-bath has been to build a draught cupboard over it, but, as I have before said, there is constant danger of the fumes from one vessel affecting the contents of the vessels near it. To obviate this and other difficulties, I have devised the arrangement shown in Fig. 4. Some four feet above the steam-bath is a wooden box or chamber *f*, *f*, communicating as shown in the figure with a draught shaft *a*, at a point not immediately above the steam-bath, but a little to one side. In the bottom of this chamber square holes are cut, through which the upper ends of the wooden frames *g*, *g*, *g* pass freely. These frames swing on pins resting on the bottom of the box. The wooden frames in turn support the stoneware funnels *h*, *h*, *h*. The upper ends of the necks of these funnels have projecting portions or ears which rest on the movable pegs *i*, *i*, working at different heights in the sides of the frames. The ears of the funnels slide up and down in grooves, so as to keep the funnels in position when being raised or lowered from one level to another. By these means the mouth of the funnel may be placed over a shallow basin, or raised so as to accommodate a tall-necked flask, as occasion requires. A continual current of air passes up through the funnels, carrying off the fumes from the vessels beneath them, so that the fumes from one vessel are entirely cut off from the neighbouring vessels. The funnels and frames can be swung back to the position shown at the right hand of Fig. 4, and may be held there by the wooden catch *k*. This enables the worker to perform conveniently any operation, such as filling up the vessel or stirring its contents without taking it away from the bath. The door *l*, *l*, swinging on leather hinges, gives access to the interior of the chamber, and permits of the frames and funnels being removed bodily by simply withdrawing the supporting pins on which they swing. No condensation takes place either in the funnels, the frames or the draught box, unless the draught is insufficient, or the steam is allowed to escape from the steam-bath much more freely than is necessary. Even in these cases condensation only takes place in winter, if the temperature of the laboratory be allowed to fall uncomfortably low. In any case the condensed drops do not fall into the evaporating vessel.

Fig. IV.



Figs. 6 and 7 give a front and bird's-eye view of an arrangement for supplying the laboratories with water at a high and constant pressure. The pressure at which the water is supplied by the street main is liable to daily and hourly variation, and is frequently cut off without warning, or does not rise to the level of the laboratories. In order to obviate the very great inconvenience and delay caused by this state of things, water is pumped up from a large low level cistern by the force pump *a*, *a*, driven by the same gas engine which drives the Blackman air propeller above mentioned. The water is pumped in at the bottom of the tank *b*, *b*, *b*, and, as it rises, compresses the air in the tank, forming an elastic air cushion. As soon as the pressure reaches a certain point, regulated by the position of the ball *c*, the conical valve *d* rises and shuts off the gridiron valve *e*, *e*, thus cutting off the water supply. In practice it has been found that the apparatus works much more smoothly if the gridiron valve be adjusted so as never to close entirely. There is thus a slight, but constant circulation of water from the cistern through the pump and tank and back to the cistern. The pipes *f*, *f* are the supply pipes to the laboratories. If a small quantity of water be drawn off, the elastic air cushion keeps the pressure practically constant, and gives, should more water be drawn off, the valves *d* and *e* time to act. The pressure at which the water leaves the tank is kept, in the Edinburgh University Laboratory, at twenty-five pounds to the square inch, but can easily be increased.

A hose is kept constantly attached to tank *b*, so that in case of fire a powerful stream of water can be immediately directed on almost any part of the new buildings. The general arrangements of the working tables, a front and side view of which are given in Fig. 3 (*a*, *β*), do not here require explanation, but there are some points in connection with these tables which are novel and may be briefly described.

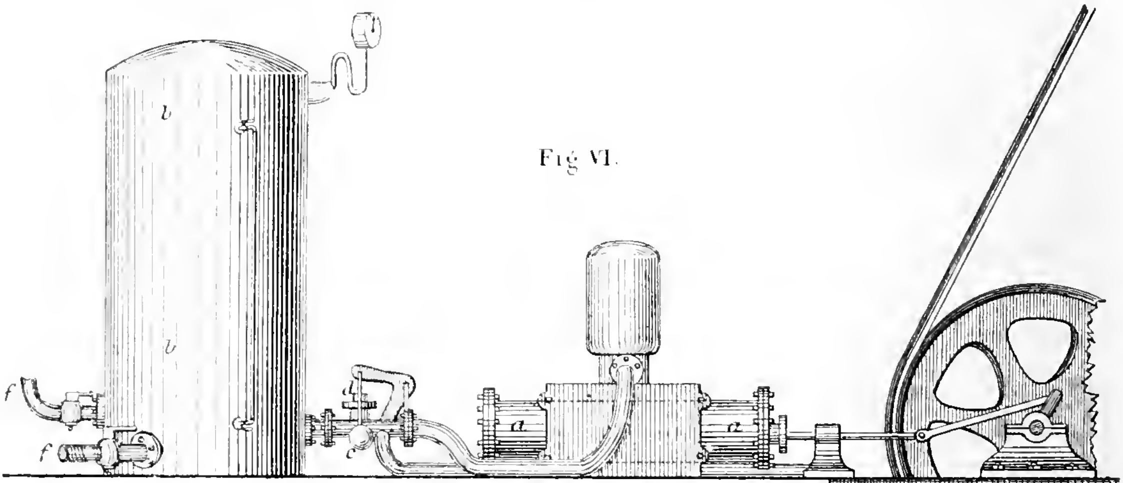


Fig VI.

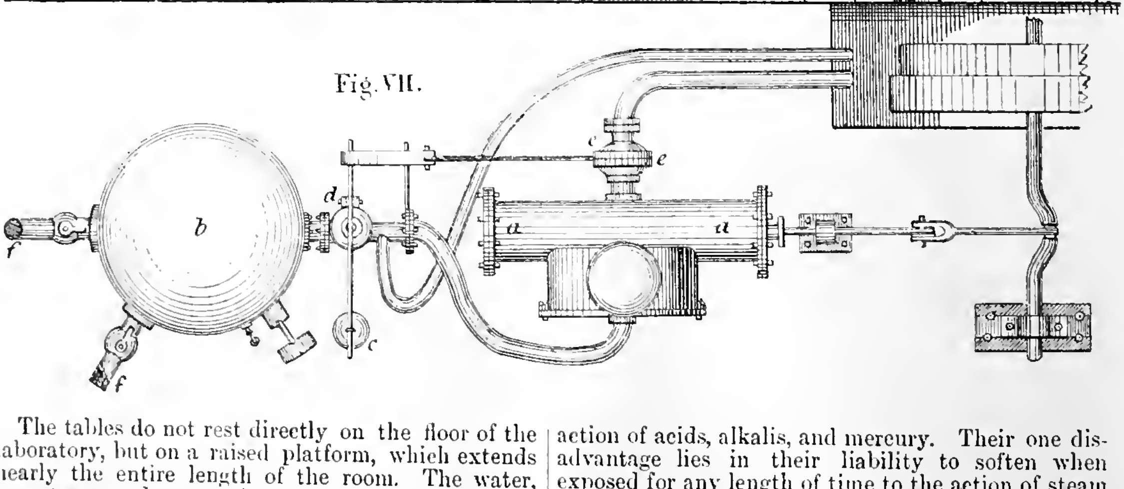

Fig. VII.

The tables do not rest directly on the floor of the laboratory, but on a raised platform, which extends nearly the entire length of the room. The water, gas, steam, and waste pipes run along the concrete floor beneath this platform. All these pipes can be laid bare at a moment's notice. The steam water and waste pipes are led along each end of the tables, and the two former pass up through the platform into the compartments *f*, *f*, *f*, which are rather projections from, than parts of, the tables themselves. These pipes are thus entirely shut off from the cupboards and drawers, etc., of the tables, and can be removed bodily without interfering with the tables in the slightest degree, and without opening a single drawer or cupboard. The porcelain sinks, of which there are four on each table—that is, one at the end of each working bench—rest loosely in holes cut in the table, and are therefore easily removed. Communication between each sink and the open waste pipe or gutter is effected by means of a short piece of stiff rubber hose or piping *g*, which passes at its upper extremity over the neck of the sink, while its lower extremity is inserted into the collar piece *h*, resting on the platform, and having its lower end hanging freely in the course of the gutter below. These collar pieces, the open gutters *i*, *i*, and the waste pipes to which these latter lead, are made of a composition of alternate layers of coarse brown paper and asphalte. Some of these pipes were brought from Germany, but Messrs. Barton & Sons, Edinburgh, have succeeded, without much difficulty, in manufacturing them. Pipes made of this material combine the advantages accruing from the use of lead or stoneware pipes, as they may be bent and jointed with the greatest facility, and resist the action of acids, alkalis, and mercury. Their one disadvantage lies in their liability to soften when exposed for any length of time to the action of steam or hot water. Hot water may be run down them at intervals without injury, but a constant flow of hot water or steam, or contact with a hot pipe, may lead in time to their collapse. In practice, however, by using the most ordinary precautions, such a contingency may be easily avoided, though, of course, it is certain to occur if these pipes are laid alongside of, or across, a hot pipe, or are used as a means of carrying off an escape of steam. By the arrangements described above, stoppages in the waste pipes are made almost impossible, and in any case repairs can be effected with a minimum of interference with the work of the laboratory.

With regard to the gas supply to the tables, it will be noticed by reference to Fig. 3. *a* and *b*, that while the nozzles are at the back of the tables underneath the reagent shelves, the wheel taps *k* are all at the front. In order to secure this very convenient arrangement, it was necessary that the cross pieces from the taps to the nozzles should pass through the woodwork, between and behind the drawers. With this exception the gas pipes are all easy of access. Fig. 8 gives a view of the gas, steam, and water supply to a stone table intended for combustions and similar operations. These arrangements for gas supply are very much the same as those adopted in the Chemical Laboratory of the University of Strasburg, from an inspection of which I have derived much most valuable suggestion. Fig. 10 shows a convenient arrangement of draught, gas, and steam supply to a small draught cupboard. It will be observed that there are no projecting nozzles or taps on the floor of the cupboard, these being all outside.

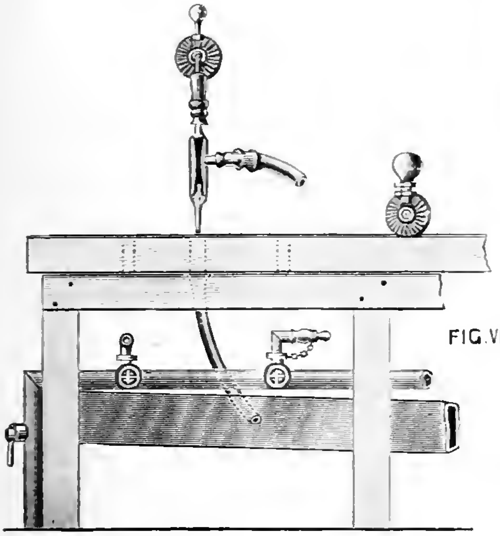

FIG. VIII

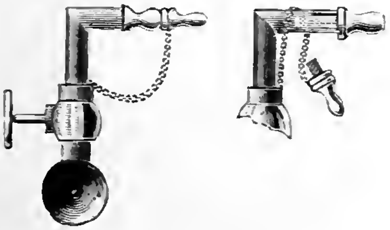

FIG. IX.

The very convenient form of small steam bath shown in this figure is made of copper, and provided with a set of porcelain rings. The steam flows in by *a*, and the condensed water running out by *b*, *b* and flowing through the small indiarubber tube is finally led into the small waste pipe *c*, *c*. This form of steam bath is described by the late Professor Pebal in his elaborate account of the Chemical Laboratories of the University at Gratz. Fig. 11 gives a view of another piece of apparatus also described by Professor Pebal, which has been found extremely useful. It is made of a peculiar light kind of porous clay, glazed on the outside. When in use it rests on an iron stand. On lighting an ordinary Bunsen burner beneath it the flame impinges upon the circular and unattached disc *m*, and not directly on the vessel which is to be heated. The heated gases are thus distributed very uniformly over the bottom of the vessel or flask. This apparatus answers all the purposes of a small sand bath, but is much

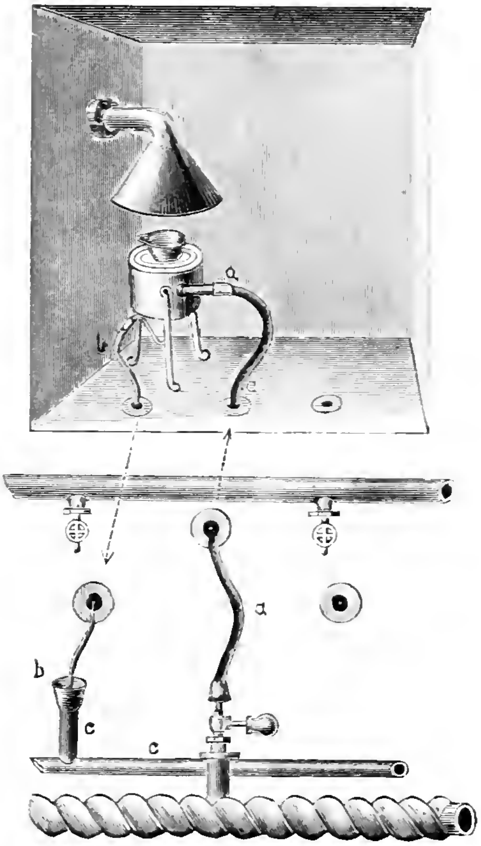

FIG. X.

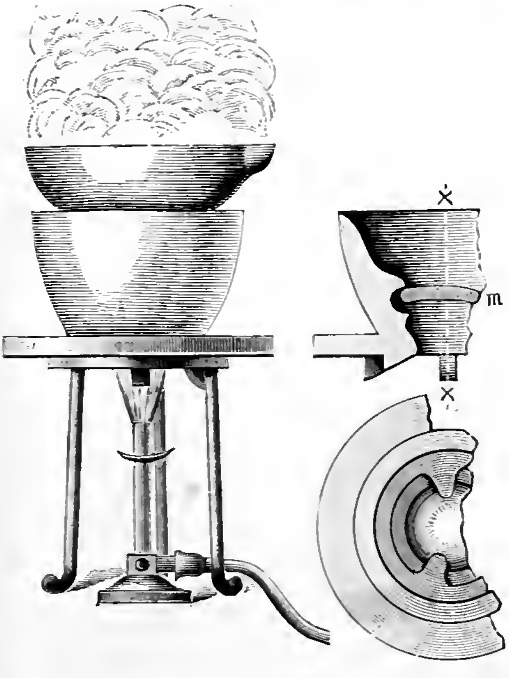

FIG. XI.

cleaner and more easily regulated. Solutions may be evaporated to dryness on it, even in glass vessels, without spirting and without cracking the glass.

Improved Filtering Apparatus.

This will be best understood by a reference to Figs. 12 and 13. The bell-jar A (Fig. 12) rests during filtration on a square block C, of hard wood, preferably Spanish mahogany, 25cm. square and 25mm. thick. The cross pieces *c*, *c* are of the same wood and prevent warping. Over C is laid a sheet of soft vulcanised rubber *d* of good quality, and not less than 3mm. thick. In the centre is a circular disc *e*, also of hard wood, 13cm. in diameter and about 20mm. thick, which is held in position by four strong brass screws, which pass down through the rubber into the square block below. In order to prevent air leaking through the holes thus made, they are rendered quite air-tight by embedding the screw heads, which are sunk slightly below the surface of *e*, in red lead, and by laying, previous to screwing down, layers of red lead on both sides of the rubber sheet. The red lead should not, however, spread beyond the disc *e* on either side of the rubber sheet, so that the latter lies quite free except where it is held down by the disc. In *b* is fitted a single bore rubber cork holding the brass tap *f*. This tap is simply an ordinary brass tap, converted into a three-way tap by boring a hole S through one outer wall and through one wall of the plug. It enables the operator to establish communication between—(1) The bell-jar and pump; (2) The outer air and both bell-jar and pump; (3) The outer air and pump, the bell-jar being shut off; (4) The outer air and bell-jar, the pump being shut off. After fitting in the cork and tap, the knee-piece *h* is screwed on. The object of this knee-piece will be explained later on. If the mouth *a* be closed by a rubber stopper, and the tap *f* connected by a rubber tube with a water-pump or other exhausting apparatus, as the pressure inside diminshes, the rubber sheet bulges up inside the bell-jar, and pressing against the lower edge, closes up any interstices due to irregularity on its own surface, or to imperfect grinding of the glass. A well-made water pump will give within half-an-hour a high degree of exhaustion, and this without the use of any lubricant whatever. Where a very high degree of exhaustion is required, the application of a little grease outside round the lower edge of the bell-jar is advisable. The apparatus in this form can, therefore, be used for drying substances in vacuo, etc. For the purpose of rapid filtration such complete exhaustion is not, as a rule, required. It is, indeed, often positively detrimental, and defeats the object in view. In practice the most convenient, though not the simplest mode of using the apparatus for filtration, is that shown by Fig. 13. The funnel is supported by a small conical rubber stopper *i* in the upper and enlarged end of the tube *k*, which is in turn supported at the mouth *a* of the bell-jar by the larger rubber stopper *l*. The hole in this stopper should be sufficiently wide to permit of the glass tube *k* sliding easily up and down in it. The lower end of the tube should be ground off at an angle and bent as shown in the figure. It is then easy to bring the end of the tube in contact with the side of the vessel in which it is desired to collect the filtrate, and thereby to entirely obviate any danger of loss by spirting.

All the essential parts of the apparatus have been now described, everything else which is required for

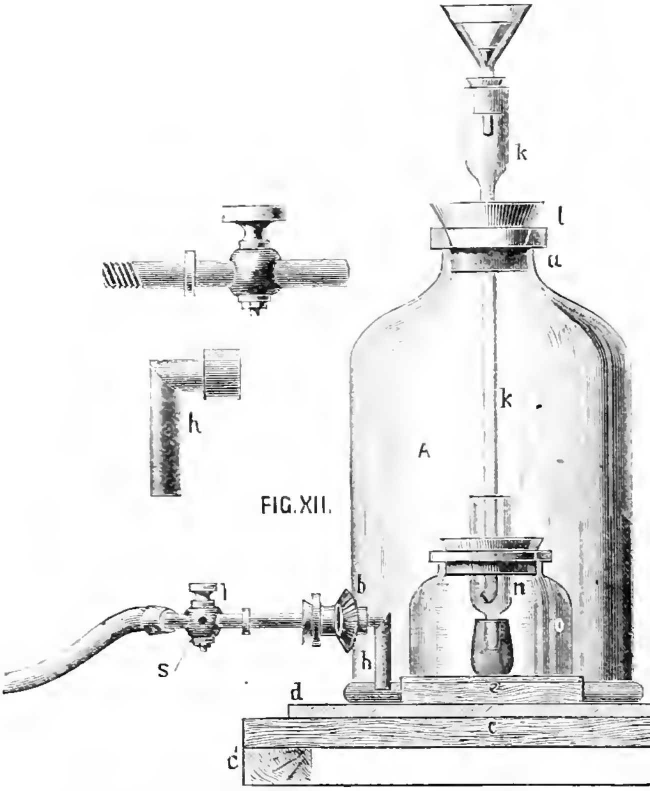

FIG. XII.

FIG. XIII.

filtration being either in ordinary laboratory use, or else can be made with but little time and trouble, and at almost no cost.

Before commencing operations it is well to slightly moisten the rubber sheet *d* with water. This is not by any means absolutely necessary, but causes a quicker gripping of bell-jar and rubber. The tap being in position No. 2, and connected with a water pump in full action, filtering is commenced by first filling up the filter nearly full with the liquid to be filtered, and then establishing communication between the pump and the bell-jar by turning the tap to position No. 1. During the operation of transferring the precipitate on to the filter, it is often necessary to lessen the rate of filtration by diminishing or destroying the difference of pressure outside and inside of the bell-jar. This can be quickly and easily done by giving the tap a half turn back to position No. 2, and thus allowing air to rush in both to the pump and to the bell-jar. The use of the knee-piece *h* will be now apparent, for by it the inrush of air is diverted away from the vessel inside, which might otherwise be blown against the side of the bell-jar, and upset or broken. As it is, however, the vessel inside is not at all affected by the inrush of air, however suddenly the tap be opened. In this connection another use of the knee-piece may be pointed out. Several of the otherwise very convenient and inexpensive high-pressure water pumps now so much used have a tendency to allow the water to run back under certain conditions, especially when a high degree of exhaustion is attained. Filtering directly in the usual way into an exhausted flask, such an accident would cause the loss of an analysis, and a valve is therefore usually placed between the pump and the flask. Such a valve is quite unnecessary while using the above apparatus. The running back of the water can be at once stopped without diminishing the pressure inside the bell-jar, by giving the tap a quarter turn so as to admit air to the pump only. Even if water does run back into the bell-jar, no harm is done, and if the knee-piece be turned downwards as shown in the figure, the pump will suck back the water again almost to the last drop.

It is sometimes necessary in quantitative analysis to filter a small quantity of liquid directly into a small weighed platinum basin or crucible—for instance, in filtering the alkaline chlorides from the last traces of magnesia in a silicate analysis, or to take another example in the purification of minute quantities of alkaloids.

This may readily be done by the arrangement shown in Fig. 12.

In order to avoid loss by spirting, the tube does not dip directly into the crucible, but into the glass tube *n*. This tube may be made out of a broken pipette, and is supported by a loosely-fitting cork in the small bell-jar *o*, which may be most conveniently made by cutting off the lower half of an ordinary wide-mouth bottle. When the filtration is over the small funnel and cork should be removed, and the wide part of the tube *k* washed with a very little water, which serves at the same time to wash down the inside of the tube *n*. By this means the amount of wash-water is reduced to a minimum. In the estimation of alkaloids the solvent is often chloroform or ether, which dissolve indiarubber, so that in such cases a small ordinary cork should be substituted for the rubber stopper. It may be further pointed out that with this apparatus it is an easy matter to filter liquids containing hydrofluoric acid, by using a platinum funnel and filtering directly into a platinum basin or other platinum vessel.

The apparatus as above described has been in general use in the Chemical Laboratories of the University of Edinburgh for the last four or five years, and has been proved to meet the simplest requirements of qualitative analysis equally with those of the most exact quantitative analysis.

The following has been found a convenient method of preserving sulphuretted hydrogen water. The bottle A (Fig. 14) is filled up to the neck with the sulphuretted hydrogen water. The double-bored stopper bearing the tubes *a*, *a*, *a* and *b*, *b*, *b* is then loosely inserted. The tube *a*, *a*, *a* is then connected with the ordinary coal-gas supply, and the air in the neck of the bottle displaced by gas. While this is taking place, suction is applied at the end or ends of the tube *b*, *b*, *b*, so as to convert it into a syphon, after which it is closed by an ordinary nipper tap. The stopper is now firmly pressed into the neck of the bottle. By this arrangement the sulphuretted hydrogen solution is preserved from oxidation, and can always be run off perfectly clear, even though left standing for months. By the use of a T tube, as shown in the figure, the sulphuretted hydrogen solution can be supplied from one bottle to both sides of a working table. The gas tap should, as a rule, be kept closed, and need only be opened for an instant whenever the sulphuretted hydrogen water ceases to flow. The tap should be lubricated with vaseline, and not with grease. Should the sulphuretted hydrogen water become turbid, it may be safely concluded that air has leaked in owing to some imperfection in the rubber connections.

Journal and Patent* Literature.

I.—GENERAL PLANT, APPARATUS, AND MACHINERY.

Improvements in Apparatus for Purifying Water. H. J. Allison, London. From J. H. Blessing, Albany, U.S.A. Eng. Pat. 15,215, Nov. 23, 1886. 8d.

THE improved apparatus consists of a cylinder containing a porous body, such as sand, and fitted with a single reversing valve serving for both induction and

---

* Any of these specifications may be obtained by post, by remitting the cost price, *plus* postage, to Mr. H. Reader Lack, Comptroller of the Patent Office, Southampton Buildings, Chancery Lane, London, W.C. The amount of postage may be calculated as follows:—

If the price does not exceed 8d.........	½d.
Above 8d., and not exceeding 1s. 6d...	1d.
,, 1s. 6d., ,, ,, 2s. 4d...	1½d.
,, 2s. 4d., ,, ,, 3s. 4d...	2d.

eduction purposes; the base of the filtering cylinder is formed by a grating, the holes of which are fitted with plungers to which a reciprocating motion can be imparted in order to keep the passages free. The filtering medium is cleaned by a reversal of the current of water combined with agitation secured by means of endless chains passing through the body of the media.—C. C. H.

II.—FUEL, GAS, AND LIGHT.

Improvements in Illuminant Appliances for Burners. O. Imray, London. From C. A. von Welsbach, Vienna, Austria. Eng. Pat. 3592, March 13, 1886. 6d.

This specification contains the results of the researches of C. A. von Welsbach since filing the Provisional Specification 15,286, 1885, and has reference to the employment of hoods or caps made by impregnating fabric with solutions of the salts of certain rare metals. A cap which is flexible when incandescent is obtained by the use of thorina and magnesia, or thorina, zirconia, and lanthana, or thorina, magnesia and alumina. A greenish light is given by erbia and thorina; a yellow by thorina and lanthana; an orange by thorina and neodymia. It is not necessary to treat the impregnated fabric with ammonia, as described in the specification above referred to.—A. R. D.

Improvements in Means or Apparatus for Supplying Liquid or Gaseous Fuel to Furnaces or Fireplaces. F. Mörth, Vienna, Austria. Eng. Pat. 4135, March 24, 1886. 8d.

Underneath the firegrate of the furnace is placed a series of horizontal tubes perforated on the top. Through these perforations a mixture of superheated steam and hydrocarbon is injected, so that it impinges on the underside of the fuel on the bars, and by its decomposition greatly increases the intensity of the combustion. The mixture of steam and hydrocarbon may also be introduced above the firegrate, if desired, through a bent tube fixed in the fore part of the furnace, and so perforated on the side next the fire that the jets issue in slightly inclined rays along the surface of the grate. The improvements include a special kind of injector, which effects the mixture of the hydrocarbon and superheated steam.—A. R. D.

Improvements in the Mode of and Means or Appliances for Making Oil Gas. J. B. Fowler, Northallerton. Eng. Pat. 16,142, Dec. 9, 1886. 8d.

This specification describes a process and apparatus for mixing oil with steam and passing the same into a heated retort. Suitable arrangements are made for washing the gas and recovering any undecomposed oil. For particulars the specification must be consulted.

—A. R. D.

Utilising Hydrocarbon Gases obtained in the Distillation of Petroleum, Rosin, and the like. G. T. Beilby, St. Kitts, and J. B. McArthur, Midcalder. Eng. Pat. 3738, March 17, 1887. 4d.

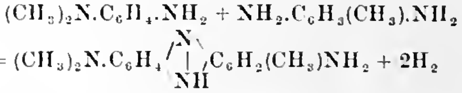
The end of the condensing worm is luted, and the uncondensed gases are drawn off by a branch pipe to a gasholder. They may be applied to any of the purposes for which ordinary coal- or oil-gas is available.—A. R. D.

IV.—COLOURING MATTERS AND DYES.

Phenazine (Azophenylene) as a Source of Colouring Matters. A. Bernthsen and H. Schweitzer. Ber. **19**, 2604—2607.

Bernthsen has attempted for a long time to prepare the compound  $C_6H_4\left\langle\begin{matrix}N\\|\\N\end{matrix}\right\rangle C_6H_4$, which, on account of its analogy with anthracene, acridine and thiodiphenylamine, might be expected to yield colouring matters. Meanwhile, Merz has prepared the homologue, methylphenazine,  $C_6H_4\left\langle\begin{matrix}N\\|\\N\end{matrix}\right\rangle C_6H_3.CH_3$, the dihydro derivative of which he obtained by heating orthotoluylenediamine with catechol: $C_6H_4(OH)_2 + (NH_2)_2C_6H_3.CH_3$  $= C_6H_4\left\langle\begin{matrix}NH\\NH\end{matrix}\right\rangle C_6H_3.CH_3 + 2H_2O$ (*Ber.* **19**, 725). The authors have obtained the same methylphenazine from a colouring matter belonging to the toluylene red group. Witt's toluylene red, $C_{15}H_{16}N_4,HCl$ (*Ber.* **12**, 931), contains an amido group, which may be eliminated by the action of nitrous acid; the resulting compound very closely resembles eurhodine (*Ber.* **18**, 1119), one of the quinoxalines (this Journal, 1886, 320—321; 377—378). The same observation was simultaneously made by Witt, who found that the acetyl compound of toluylene red resembles eurhodine. The compound obtained by the authors from toluylene red has the formula $C_{15}H_{15}N_5$. It forms beautiful garnet-red needles or prisms, which exhibit a green lustre. It possesses basic properties and dissolves in dilute acids forming a violet liquid; but with concentrated sulphuric acid it gives a red-brown solution, which when diluted becomes at first green, then blue and finally violet. Alcohol forms a red, and ether a yellowish-red solution with a golden-yellow fluorescence. Like eurhodine, it sublimes without decomposition. Its formula is therefore  $N(CH_3)_2.C_6H_3\left\langle\begin{matrix}N\\|\\N\end{matrix}\right\rangle C_6H_3(CH_3)$. By the oxidation of paraphenylenediamine, instead of nitroso-(amido)-dimethylaniline with metatoluylenediamine, a simpler toluylene blue, and from this a toluylene red, is obtained, the $N(CH_3)_2$ group being replaced by NH_2. When this compound is treated with nitrous acid, methylphenazine is obtained in the form of yellow needles, melting and subliming at 117° to 117·5°. It possesses basic properties, and forms a bluish-red solution with concentrated sulphuric acid. The compound is obviously homologous with the azophenylene (phenazine) described by Claus, which is therefore the basis of the toluylene red colouring matters. The formation of toluylene red is represented by the following equations:—

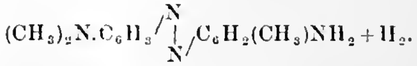
(1)



$$(CH_3)_2N.C_6H_4.NH_2 + NH_2.C_6H_3(CH_3).NH_2$$
$$= (CH_3)_2N.C_6H_4\left\langle\begin{matrix}N\\|\\NH\end{matrix}\right\rangle C_6H_2(CH_3)NH_2 + 2H_2$$

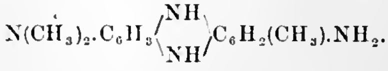
(Toluylene blue).

(2) Toluylene blue—



$$(CH_3)_2N.C_6H_3\left\langle\begin{matrix}N\\|\\N\end{matrix}\right\rangle C_6H_2(CH_3)NH_2 + H_2.$$

Leucotoluylene red has consequently the formula:

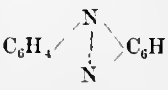


$$N(CH_3)_2.C_6H_3\left\langle\begin{matrix}NH\\NH\end{matrix}\right\rangle C_6H_2(CH_3).NH_2.$$

The analogy with leucomethylene blue, leucothionine, and so on, is obvious. The part played by sulphur in the methylene blue group is taken by an imido group in the toluylene red compounds. It follows also that the safranines are derivatives of phenazine.—S. Y.

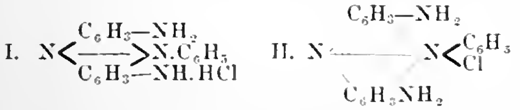
Constitution of the Safranines. A. Bernthsen. Ber. **19**, 2690—2693.

In a previous paper (*Ber.* **19**, 2607) the author has shown that very probably the safranines are derived from *phenazine*—



$$C_6H_4\left\langle\begin{matrix}N\\|\\N\end{matrix}\right\rangle C_6H_4$$

from which the colours of the toluylene-red class are also derived. The simplest member of this class of colours is Witt's phenosafranine $C_{18}H_{14}N_4HCl$, which may be regarded as derived from the simplest member of the toluylene-red class, *diamidophenazine*, $C_{12}H_6.N_2.(NH_2)_2$, by the exchange of one atom of hydrogen with C_6H_5. This substitution may, according to theory, take place in very different positions, but owing to the discovery of Nietzki, that the indamines are intermediate products of the safranine reaction, it appears probable that it takes place with that nitrogen atom which unites the two other phenyl groups. Thus, leucophenosafranine would be formed by the oxidation of equal molecules of *p*-diamidodiphenylamine (leuco-indamine) and aniline : $NH_2.C_6H_4.NH.C_6H_4.NH_2 + C_6H_5.NH_2 = NH_2.C_6H_3:(NH)(N.C_6H_5):C_6H_3.NH_2 + 4H$. If this is correct, only primary amines are capable of forming safranine when oxidised with leuco-indamine; and, according to Nietzki, such is really the case. The ordinary formation of safranine by oxidation of one molecule paradiamine with two molecules monamine, would be expressed in the following manner :—$NH_2.C_6H_4.NH_2 + 2C_6H_5.NH_2 = NH_2.C_6H_3(NH)(N.C_6H_5)C_6H_3.NH_2 + 6H$. This theory explains why, in the safranine reaction, in one of the monamines, the para-position to the nitrogen atom must be free, although the monamine need not be a primary one. It also accounts for the presence of two amido groups. The similarity between leucophenosafranine, $NH:(C_6H_3.NH_2)_2:NC_6H_5$, and leucothionine (methylene blue), $NH:(C_6H_3.NH_2)_2:S$, is very pronounced. Both can be obtained from *p*-diamidodiphenylamine, the former by oxidation with aniline, and the latter by warming with sulphur. For the constitution of the colours themselves, which contain two H atoms less than the leuco-compounds, the two possible expressions may serve—



$$\mathrm{I.}\quad N{<}\begin{matrix}C_6H_3-NH_2\\ \rule{2em}{0.4pt}\\ C_6H_3-NH.HCl\end{matrix}{>}N.C_6H_5 \qquad \mathrm{II.}\quad N\begin{matrix}C_6H_3-NH_2\\ \rule{4em}{0.4pt}\\ C_6H_3.NH_2\end{matrix}N{<}\begin{matrix}C_6H_5\\ Cl\end{matrix}$$

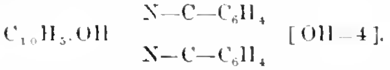
The presence of two intact amido-groups in safranine points to formula II., which shows this substance to be a real phenazine derivative, a *diamidophenylphenazonium chloride*, which would explain its non-basification by alkalis. However, the complete analogy with the methylene blue group speaks for formula I. Nietzki at one time supposed safranines to be triphenylamine derivatives, but leucosafranine cannot be triamidotriphenylamine, $N.(C_6H_4.NH_2)_3$, because it contains two H atoms too little; but it nevertheless can be considered as a derivative of diphenylamine, as the following change in the formula will show :—$C_6H_5.N:(C_6H_3.NH_2)_2:NH$ = leucosafranine.—T. L. B.

Constitution of Nitranilic Acid. R. Nietzki. Ber. **19**, 2727.

When the *diamidotetroxybenzene hydrochloride*, produced by reducing nitranilic acid, is distilled over zinc dust, a small quantity of a crystalline base is obtained. This was found to be *p*-phenylenediamine, thus confirming the results of Hantzsch (*Ber.* **19**, 2398), who has shown that nitranilic acid is *p-dinitrodihydroxyquinone*, he having obtained it by treating dihydroxyquinoneterephthalic acid with nitric acid. With such a reaction as the zinc-dust distillation, the possibility of intermolecular change is not avoided, but the whole behaviour of the diamidotetroxybenzene shows that it is no orthodiamine. Phenanthrenequinone oxidises it simply to *di-imidodihydroxyquinone*, forming no condensation products (Hinsburg's reaction for orthodiamines). A simpler reaction for these bodies is obtained with croconic acid. The potassium salt of this acid on simply mixing with a solution of an orthodiamine salt gives rise to the formation of a dark coloured precipitate of the corresponding croconquinoxaline. With diamidotetroxybenzene, however, a yellow crystalline precipitate, of the croconate, only was formed. Ladenburg's reaction with benzaldehyde (*Ber.* **11**, 600) also gave no result.—T. L. B.

On the Eurhodines and Laurent's Naphthase. Otto N. Witt. Ber. **19**, 2791—2796.

The sulphonic acid of the ortho-naphthylenediamine, obtained by reducing azo-colouring matters derived from naphthionic acid, is completely converted by condensation with phenanthrenequinone into *diphenylenenaphthazine sulphonic acid.* When this sulphonic acid is fused with caustic potash, the corresponding eurhodol is easily and quantitatively obtained. The melt is at first yellow, but suddenly becomes of a cinnabar-red colour. The reaction is then finished; the mass dissolved in water and acidified with an excess of HCl, deposits the hydrochloride of the new eurhodol as an insoluble cinnabar-red powder. This eurhodol is quite insoluble in all solvents, but may be obtained in silky needles by basifying a boiling solution of the hydrochloride in phenol, with aniline. It forms fine pure yellow needles, subliming in the characteristic voluminous form. Concentrated sulphuric acid dissolves it with an intense pure blue colouration, which a very slight amount of water changes suddenly into a splendid carmine red. The sulphonic acid, obtained by heating the above blue solution until it has become yellow, dyes wool a sulphur-yellow colour. Friction renders it so electric that on rubbing in an agate mortar the particles disperse themselves in all directions. Its constitution is as follows :—



$$C_{10}H_5.OH\begin{matrix}N-C-C_6H_4\\ N-C-C_6H_4\end{matrix}\qquad[OH-4].$$

By using β-naphthoquinone instead of phenanthrenequinone in the above reaction, the sulphonic acid of α-β-naphthazine was obtained, which, on fusion with caustic potash, yielded a similar eurhodol. The mother substance of these bodies—viz., naphthazine,

$$C_{10}H_6\begin{matrix}N\\ |\\ N\end{matrix}C_{10}H_6$$

the author has found to be identical with the compound obtained by Laurent from the distillation of α-nitronaphthalene with quicklime, and by him named naphthase (*Ann. Chem. Pharm.* **9**, 384). It is best obtained in the following manner :—4·6grms. *o*-naphthylenediamine-dihydrochloride are dissolved in the least possible quantity of water. This solution is then mixed with 50cc. glacial acetic acid, 5grms. sodium acetate crystals, and well cooled in a freezing mixture. A likewise cold solution of 3·2grms. β-naphthoquinone in 50cc. of glacial acetic acid, is then run into it, and the whole allowed to stand a few hours. The new azine is obtained as a dark brown precipitate, which, after washing with alcohol, is purified by sublimation, forming long yellow needles or woolly flocks, which melt at 275°. When quickly heated it can be distilled. Sulphuric acid dissolves naphthazine, forming a pure violet-coloured solution, which, on dilution, becomes orange-yellow, the free base being finally precipitated. Alcohol, benzene, and acetic acid dissolve it but sparingly. It is more soluble in phenol and aniline. Naphthalene dissolves it readily at the boil, depositing it in beautiful needles on cooling, which are then freed from the solvent by washing either with alcohol or benzene.—T. L. B.

Diphenylmetaxylylmethane and Diphenylorthoxylylmethane. W. Hemilian. Ber. **19**, 3061—3075.

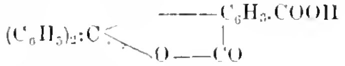
The author has already described the formation of diphenylparaxylylmethane from diphenylcarbinol and paraxylene, (*Ber.* **16**, 2360).

Diphenylmetaxylylmethane $(C_6H_5)_2.CH.C_6H_3(CH_3)_2$ is obtained by heating together diphenylcarbinol, metaxylene and phosphoric anhydride. It crystallises from alcohol or ether in large prisms melting at 61·5°. On oxidation with chromic acid mixture it yields a resinous mass, which is partly soluble in a concentrated soda solution. By extracting the insoluble portion with ether, *diphenylmethylphthalide* $C_{21}H_{16}O_2$ is obtained. This compound is isomeric with the product obtained by the oxidation of diphenylparaxylylmethane. It crystallises from alcohol in lustrous prismatic crystals, melting at 179°, and distilling without decomposition above 360°.

Methyltriphenylmethane carboxylic acid $(C_6H_5)_2CH.C_6H_3.CH_3.CO.OH$ is obtained by first heating diphenylmethylphthalide with a concentrated solution of alcoholic soda and then reducing the resulting sodium methyltriphenylcarbinolorthocarboxylate with zinc dust. The solution thus obtained is decomposed with hydrochloric acid and the precipitate recrystallised from alcohol. Methyltriphenylmethanecarboxylic acid forms large tabular crystals melting at 203°, and distilling without decomposition at a higher temperature. It is readily soluble in hot alcohol, ether and glacial acetic acid. It is a monobasic acid forming crystalline salts, which are mostly sparingly soluble in water. By careful oxidation it is easily reconverted into diphenylmethylphthalide. By the action of dehydrating agents, derivatives of methylphenylanthracene are obtained. Concentrated sulphuric acid converts it into *methylphenylanthranol* $C_{21}H_{16}O$, the yield of which is, however, extremely small. By oxidising methylphenylanthranol with chromic acid, *methylphenyloxanthranol*—

$$CH_3.C_6H_5 < \begin{matrix} C(OH).C_6H_5 \\ CO \end{matrix} > C_6H_4$$

is formed. It crystallises from glacial acetic acid in large colourless prisms melting at 213°, is insoluble in alkalis, dissolves in concentrated sulphuric acid, forming a purple solution, and is converted into methylphenylanthranol by reducing agents. The portion of the products of oxidation of diphenylmetaxylenemethane which is soluble in soda is decolourised with animal charcoal and saturated with hydrochloric acid. The flocculent precipitate is recrystallised from glacial acetic acid and alcohol, crystals of *diphenylphthalidecarboxylic acid* being formed, having the formula—



$$(C_6H_5)_2{:}C \begin{matrix} -C_6H_3.COOH \\ | \\ O-CO \end{matrix}$$

and melting at 228°. This acid is monobasic, dissolves readily in alcohol, ether, benzene and glacial acetic acid, and forms salts which are mostly insoluble in water. When distilled with excess of barium hydroxide, it yields benzophenone and benzene, whilst by careful fusion with caustic alkalis the salts of isophthalic and benzoic acids are formed, besides benzophenone.

Triphenylmethanedicarboxylic acid $(C_6H_5)_2CH.C_6H_3(COOH)_2(1:2:4)$ is obtained by treating an alkaline solution of the preceding anhydro acid with zinc dust, filtering the solution and decomposing the filtrate with hydrochloric acid. The white curdy precipitate thus obtained is crystallised from alcohol, when it forms slender lustrous needles which melt at 278°, and are readily soluble in alcohol and glacial acetic acid. Its salts are, as a rule, easily soluble in water, but the silver salt is insoluble in water and alcohol. When distilled with excess of barium hydroxide, triphenylmethane is obtained. On oxidation it is converted into diphenylphthalide carboxylic acid. It dissolves in concentrated sulphuric acid, forming a greenish-yellow solution, which on warming changes first to green, then indigo blue and finally assumes a purple colour.

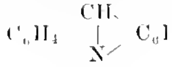
Diphenylorthoxylylmethane $(C_6H_5)_2CH.C_6H_3(CH_3)_2$ is obtained by heating together diphenyl carbinol orthoxylene and phosphoric anhydride. It crystallises from alcohol in long lustrous needles melting at 68·5°, and distilling above 360°, and dissolves readily in alcohol, ether and glacial acetic acid. On oxidation with chromic acid mixture it yields a solid mass, which is partly soluble in a concentrated soda solution. The residue does not, however, contain a phthalide derivative. The soluble portion consists of a mixture of several acids. By further oxidising the solution with potassium permanganate, filtering and saturating the filtrate with hydrochloric acid, a white crystalline precipitate is obtained, which on recrystallisation from boiling water yields *triphenylcarbinoldicarboxylic acid* $(C_6H_5)_2C(OH).C_6H_3(COOH)_2$. This acid is crystalline, readily soluble in alcohol, ether and glacial acetic acid, sparingly soluble in benzene, and almost insoluble in petroleum spirit. Its salts form amorphous precipitates mostly insoluble in water. It melts at 180°, and is at the same time resolved into water and the anhydride. It is not changed by reducing agents. When distilled with excess of barium hydroxide it yields triphenylcarbinol melting at 158°, the following reaction taking place:—

$$(C_6H_5)_2C(OH).C_6H_3(COOH)_2 = 2CO_2 + (C_6H_5)_3C.OH.$$

—D. B.

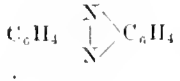
A New Synthesis of Thiodiphenylamine. A. Bernthsen, Ber. **19**, 3255—3256.

Recent experiments have shown the similarity between the chromogen anthracene and the acridine compounds—



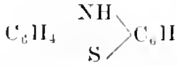
$$C_6H_4 \begin{matrix} CH \\ | \\ N \end{matrix} C_6H_4$$

phenazine—



$$C_6H_4 \begin{matrix} N \\ | \\ N \end{matrix} > C_6H_4$$

and thiodiphenylamine—



$$C_6H_4 \begin{matrix} NH \\ S \end{matrix} > C_6H_4.$$

Anthracene is known to be a diorthodiphenylene compound, also the same constitution is held most probable for acridine by the formation of quinolinedicarboxylic acid, and for phenazine on account of its synthesis. By the formation of thiodiphenylamine by the condensation of *o*-amidophenylmercaptan and catechol (pyrocatechin) the author has obtained strong proof of a like combination of the atoms in this substance. The reaction, which may be expressed as follows: $NH_2.C_6H_4.SH + C_6H_4(OH)_2 = C_6H_4 < \genfrac{}{}{0pt}{}{NH}{S} > C_6H_4 + 2H_2O.$ takes place on heating in a sealed tube for thirty hours at 220—240°. Hydrogen sulphide is given off on opening the tube, and the yield is small.—T. L. B.

Quinoline Red. A. W. Hofmann. Ber. **20**, 4—20.

The above-named colouring matter was discovered by E. Jacobsen, and is obtained by the action of benzyltrichloride upon quinoline in the presence of zinc chloride. 100grms. coal-tar quinoline, boiling at 235—240°, are mixed with 25grms. dry zinc chloride, warmed upon the water bath, and 40grms. benzyltrichloride, added drop by drop, agitating the mixture well in order to keep the temperature below 120—130°. This takes about three to four hours. The tarry product is then treated with a thin milk of lime (100CaO to 1000cc. water), and the excess of quinoline distilled off with steam. The boiling limed solution is now filtered off, and the colour precipitated by the addition of hydrochloric acid in excess, as a fine crystalline powder. The zinc and lime salts are difficult to remove by mere recrystallisation, so, for analytical purposes, the colour was made without zinc chloride; but the temperature had to be raised to about 150°, and the yield was very poor. About 50 per cent. of the quinoline is recovered; deducting this, the yield of colouring matter averages 10 per cent. upon the base used. This recovered base only gave traces of colour on repeating the treatment with benzyltrichloride, a fact which pointed either to a different base being present in the raw quinoline, or that, as in the magenta process, two homologous bases were needed to form the colour. E. Jacobsen and C. L. Reimer (*Ber.* **16**, 1086) having discovered quinaldine in crude quinoline, considered that the colour was derived from this base and quinoline, as neither base *alone*, when treated with $C_7H_5Cl_3$ gave any colour. A repetition of these experiments with *pure* samples of these bases showed, however, that only about 1¼ per cent. of colour was formed, while the properties and shade of the two substances appeared somewhat different. Later on Hoogewerf and Van Dorp, having detected the presence of *isoquinoline* in the coal-tar quinoline (*Rec. Trav. Chim.* **4**, 125—129), experiments were made with this pure base, melting at 20° and boiling at 235—236°, obtained from phthalic acid by Gabriel's process. Heated alone with $C_7H_5Cl_3$ and $ZnCl_2$, isoquinoline gave no colour reaction, but a mixture of 1mol. isoquinoline and 1mol. quinaldine produced a colouration at 120°, and the yield averaged about twice as much as was obtained from raw quinoline and 8½ times as much as from a mixture of quinoline and quinaldine. The properties of the colour thus obtained are similar to those of that obtained in the ordinary way. From very dilute hot hydrochloric acid it crystallises in thin quadratic and brown leaflets or prisms, and by evaporation of the alcoholic solution, forms long pyramidal prisms. It is soluble in acetic acid, phenol and alcohol with crimson colouration showing yellow-red fluorescence, but is insoluble in ether and benzene. It dyes wool and silk a fugitive pink with indication of a yellow fluorescence, whilst the ordinary quinoline red has a slight violet tone. Both bodies show two dark ill-defined absorption bands between F and D, maximum absorption being at 540 and at 500, those shown by the iso-colour being clearer defined and more intense. Photographically, both colours act as good sensitisers for yellow, orange and yellow-green light. Bromide of silver gelatin plates dipped in solutions of both colours (1 : 12,500), and dried and exposed to the solar spectrum, were extremely sensitive to the region between E—D¼ C.

The hydrochloride of this colour is very hygroscopic, and only parts with its moisture at 120—140°. The analysis gave figures pointing to the formula—$C_{26}H_{19}N_2Cl$, which agrees with the equation—

$$C_9H_7N + C_{10}H_9N + C_7H_5Cl_3 = C_{26}H_{19}N_2Cl + 2HCl.$$

The analysis of the platinum double salt $2(C_{26}H_{19}N_2Cl)PtCl_4$ entirely confirmed this supposition; this salt precipitates from the alcohol solution of the colour as a carmine powder, entirely insoluble in water, alcohol, and hydrochloric acid. Quinoline red is reduced to a leuco-compound by treatment with zinc and HCl. When heated with an excess of alcoholic ammonium sulphide in a sealed tube to 200° for eight or ten hours, it is split up into benzylmercaptan, and a weak base $C_{19}H_{14}N_2$, which forms gold yellow brilliant leaflets, melting at 231°, subliming easily, insoluble in water, soluble in ether, benzene, CS_2, acids, and phenol. The reaction is as follows:—

$$C_{26}H_{19}N_2Cl + H_2S + 2H = C_{19}H_{14}N_2 + HCl + C_7H_5S.$$

Hydrochloric acid converts quinoline red into quinolines and benzaldehyde. Oxidation produces benzoic acid. Distillation over zinc dust gives a mixture of bases; one of them melting at 86°, has the formula $C_{17}H_{15}N$.

This colour cannot be regarded as an analogue of malachite green, in spite of its method of formation, owing to the difference in the behaviour of the two substances with ammonium sulphide—the green simply being reduced to its leuco-compound, and also on account of the stability of its salts in the presence of alkali. Further, it has been found impossible to obtain the red by the benzaldehyde and $ZnCl_2$ reaction. Its formula may therefore be expressed as $C_6H_5.CCl(C_9H_6N)(C_9H_5(CH_3)N)$, or $C_6H_5.CCl(C_9H_6N)(CH_2.C_9H_6N)$; accordingly as the condensation has taken place in the nucleus or in the methyl group of the quinaldine. Further investigation of the reduction bases may throw more light on the constitution of this colour, but attempts to obtain the yellow base of the probable formula—$C_9H_6N-CH_2-NC_9H_6$, by the action of methylene diiodide on quinoline or isoquinoline, have entirely failed.
—T. L. B.

Researches on the Relation between the Molecular Structures of Carbon Compounds, and their Absorption Spectra. Part VIII.—A Study of Coloured Substances and Dyes. W. N. Hartley, J. Chem. Soc. (Trans.), 1887, 152—200.

A COLOURED substance is one which absorbs rays at either end of the spectrum or selects rays of certain wave length from the middle of the same. All fluorescent bodies are therefore coloured, and benzene and other compounds which exhibit selective absorption of ultra-violet rays are coloured, though the eye cannot detect it, whilst coloured bodies in the ordinary sense of the term only absorb rays limited by the violet and red ends of the spectrum; thus there are visible and invisible colours. Selective absorption bands seem to be the effect of molecular vibrations, and depend upon the rate of the latter; so that if we desire to convert benzene or such a substance into one visibly coloured, it is necessary to alter its rate of vibration so that its molecule will absorb rays with oscillation frequencies occurring within the limits of visibility. A *chromogen* is therefore an "invisible" coloured substance, and a *chromophor* is an atom, or group of atoms, which reduces the rate of molecular vibrations to within the visible limit. Oxygen and nitrogen, when united in a certain manner are chromophors, and when united to carbon under certain conditions, as in uric acid, constitute a chromogen readily changed into murexide. The condensation of oxygen tends to form highly coloured substances, as shown in the ferrates, manganates, red-lead, etc. In the benzene nucleus, the introduction of N and O atoms by reducing the rate of the molecular vibration to within the limit of visibility—*i.e.*, to less than the rate of violet light—produces colours and dyes, as in quinone, azobenzene, etc. The author has studied a number of nearly related colouring matters of the triphenylmethane and azobenzene series. The absorption curve of triphenylmethane resembles that of benzene in its general character; but the vibration rate is much reduced by the linking of three benzene nuclei, and this rate is further reduced in the following increasing order of intensity by the introduction of imido-, amido- and hydroxyl-groups, and the combination of these imido- and amido-groups with hydrochloric acid, as in rosaniline hydrochloride. In azobenzene, as compared with benzene, the rate is also very considerably reduced, and in many members of this series the amplitude of the vibration is virtually the same, though of course not entirely alike, showing what an important influence the doubly united nitrogen has in the production of the colour. The curves of all the dyes in each series follow each other closely, the modification being such that the molecules of the greatest mass transmit the least light and vibrate less rapidly.

Uric acid exhibits an extraordinary absorptive power in layers 15mm. thick, in very dilute aqueous solution 1 : 15,000). The investigations have shown that when (absorption takes place in the visible region, the ultra-violet rays of the spectrum are also absorbed.—T. L. B.

A Blue Colouring Matter for Cotton. H. Müller. Chem. Zeit. **10**, 1400 (Société Industrielle de Mulhouse, Oct. 1886).

WHEN a solution of the diazo derivative of diamidodiphenetol $NH_2(OC_2H_5)C_6H_3—C_6H_3(OC_2H_5)NH_2$ is poured into a solution of α-naphtholsulphonic acid, in the proportion of two molecules of the sulphonic acid to one molecule of the diazo compound, a blue colouring matter is obtained, which in both acid and alkaline solution, dyes cotton directly without a mordant. The colour withstands the action of acids and soap.—S. Y.

VI.—DYEING, CALICO PRINTING, PAPER STAINING, AND BLEACHING.

Improvements in Dyeing Textile Goods and Materials. Henry Kershaw, Salford. Eng. Pat. 3732, March 17, 1886. 4d.

THIS invention relates to the dyeing of cotton and other vegetable fibres and of goods and yarns made therefrom. Chromium sulphate and ferric sulphate or other salts of chromium or iron, are dissolved in water, and sodium bicarbonate or commercial soda added, the quantity of alkali used being such that precipitation of the oxides does not take place. The goods —say for example, cotton piece goods—are thoroughly saturated, by passing the goods through the solution or by other suitable means, afterwards squeezed and suitably dried. The goods are then treated with a weak boiling solution of silicate of soda, carbonate of soda or a solution of soap. By these means greenish-grey colours are obtained, the silicate of soda solution producing greener shades than the sodium carbonate or the soap solution.—S. H.

VII.—ACIDS, ALKALIS, AND SALTS.

Improvements in the Concentration of Sulphuric Acid and in Apparatus for that Purpose. H. J. Leslie, London. From R. Finch, Mülheim, Germany. Eng. Pat. 2207. Feb. 15, 1886. 8d.

A is an evaporating furnace, which is in connection with two towers B and C, loosely filled with any acid-proof refractory material. The first tower communicates with the escape flue D, and at the top with the second tower C, from the bottom of which there is a flue E to the chimney. The evaporating furnace A is provided with a lead tank H, which is lined with a layer of sheet asbestos I, upon which is built a thick lining K of silica brick. The top of the furnace is formed by a low arch L, lined inside with silica bricks, and covered outside with lead. At the one end of the chamber thus formed is the escape flue D, and at the other end is the deep fireplace N for the combustion of smokeless fuel. The weak acid enters the apparatus through the syphon pipes F on the top of the towers, and gradually flowing downwards, comes into intimate contact with the hot gases from the evaporating furnace, and thus becomes concentrated to a certain degree before entering the furnace proper. At the same time, sulphuric acid vapour that may have escaped with the furnace gases into the tower becomes condensed, and passes back into the evaporating furnace. The acid proceeding from the bottom of the tower B is led by a pipe O to a syphon P into the chamber, where the hot gases effect its concentration to any required degree, even to a specific gravity of 1·845. The lead tank can be extended round three sides of the furnace so as to form an external trough Q for cooling the concentrated acid, this trough being also lined with asbestos and brick. By the above-described construction, the metallic parts are said to be effectually protected from being attacked by the acid, while a considerable economy of fuel is brought about. The apparatus is also comparatively cheap.—S. H.

Improvements in the Preparation of Sulphate of Alumina. J. J. Hood and A. G. Salamon, London. Eng. Pat. 1881, Feb. 9, 1886. 6d.

THE object of this invention is the removal of iron from aluminium sulphate. This is effected by the use of meta-stannic acid or its salts. The aluminium solution, preferably concentrated, is heated, and the iron contained in it oxidised to ferric oxide by bleaching powder. No free acid must be present; and to this end, as also in order to make the aluminium sulphate somewhat basic, a slight excess of calcium carbonate is added. Meta-stannic acid in the moist state is then added in suitable quantities, and the whole mass agitated until a sample drawn shows the absence of iron in solution. The agitation is then stopped, the mass allowed to subside, and the solution of aluminium run off to be treated as may be desired. Any tin in solution may be removed by the addition of sulphuretted hydrogen. The sediment of meta-stannic acid and iron may be repeatedly used until it has taken up so much iron as to impair its efficiency. It is then treated with strong sulphuric acid, and allowed to stand for some hours. The iron sulphate is then removed by washing, and the treatment with sulphuric acid repeated if necessary. The meta-stannic acid is then again suitable for use.—S. H.

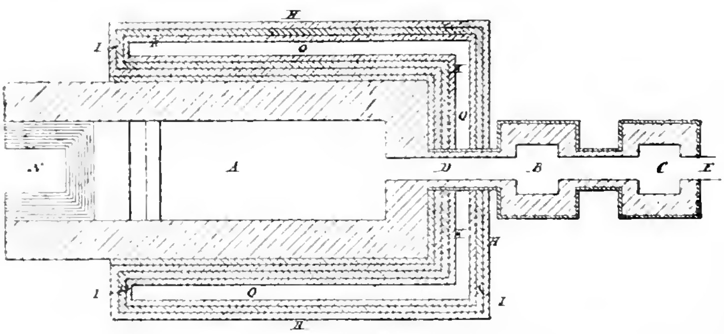

Fig 2

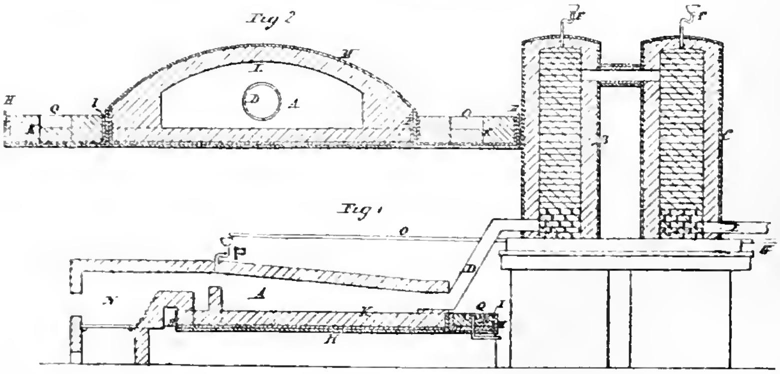
Fig 1



Improvements in obtaining Ammonia and Hydrochloric Acid from Ammonium Chloride. L. Mond, Northwich. Eng. Pat. 1048, Jan. 23, 1886. 4d.

THE inventor described in a previous specification (Eng. Pat. 65, 1886) a method for obtaining ammonia and hydrochloric acid from ammonium chloride by the aid of nickel protoxide or other metallic oxides. He now finds that these oxides can be with advantage replaced by their combinations with acids, which are not volatile at the temperatures employed in this process, such as silicic, phosphoric, boric, tungstic, antimonic and other acids. On employing these salts in place of the oxides, the process can be completed at a lower temperature. In addition to those salts, the salts of the acids mentioned with the oxides of the alkaline earths, can be used with the same advantage.—S. H.

Improvements in obtaining Ammonia and Chlorine from Ammonium Chloride. L. Mond, Northwich. Eng. Pat. 1049, Jan. 23, 1886. 4d.

With respect to a previous specification (Eng. Pat. 66, 1886) in which the action of ammonium chloride vapour on nickel protoxide and other oxides was described, it has been found that these metallic oxides may be, with advantage, replaced by their combinations with acids, which are not volatile at an elevated temperature, such as silicic, phosphoric, boric, tungstic, antimonic acids, and others. The salts of these acids with the oxides of all the alkaline earths, may be used for the same purpose.
—S. H.

Improvements in obtaining Compounds of Cobalt from Solutions of the same. G. Perry, Harwell Steventon. From M. Perry, Sydney. Eng. Pat. 1288, Jan. 28, 1886. 4d.

This invention relates to precipitating pure cobalt compounds from solutions containing cobalt together with nickel, manganese and iron. The solution to be treated is brought to the boiling-point, and while boiling, a boiling solution of sodium hydrate of 8 to 10 per cent. strength is added. The cobalt is precipitated as a hydrate, which, by continued boiling, becomes a basic sulphate. If the precipitate contains nickel, manganese, or iron, it is treated with more boiling mother-liquor containing cobalt, when the foreign metals will go again into solution, and will be replaced by cobalt precipitated from the added liquor.—S. H.

Improvements in obtaining Compounds of Cobalt from Solutions containing the same. M. Perry, Sydney. Eng. Pat. 1289, Jan. 28, 1886. 4d.

This invention refers to a method of precipitating a pure salt of cobalt from solutions containing cobalt, together with nickel and manganese. The clear solution of the sulphates is heated at the boiling temperature with metallic iron, when pure cobalt is precipitated as a hydrate, which by continued heating can be converted into a basic sulphate. As long as there is cobalt in solution, no nickel or manganese will precipitate.—S. H.

An Improved Process for Manufacturing Sulphates of Metals from their Oxides. A. M. Graham, Lewisham. Eng. Pat. 1831, Feb. 8, 1886. 6d.

This invention relates to a process by which the oxides of readily oxidisable metals, such as manganese or iron, may be converted into sulphates. In carrying out the process with reference to manganese, the peroxide of this metal in a state of fine division is mixed with finely-powdered iron pyrites and clay or flint. The intimate mixture of the different ingredients is heated in an iron pan, at first to about 400° or 500° F., the heat being then gradually increased to incipient redness, and continued for seven or eight hours. After this time, the mass is removed from the pan, allowed to cool, moistened with water, and exposed to the atmosphere until the sulphates are rendered soluble, which is usually the case in less than a fortnight. The mixed sulphates are then dissolved out, and the iron peroxidised by the usual methods. If the residue contains manganese it is treated over again in the same manner. The object of the clay or flint is to keep the mass in a sufficiently fine state of division to allow the passage of air through it.—S. H.

An Improved Process for the Production of Carbonate of Sodium or of Potassium, and Hydrate of Strontium or of Barium. E. F. Trachsel, Holloway, Middlesex. Eng. Pat. 3406, March 10, 1886. 6d.

An intimate mixture of sulphate of soda and sulphate of strontia, or of baryta and coal, is ignited for the reduction of the sulphates. The mass is then lixiviated with hot water and allowed to cool, when crystals of strontium or barium hydrate are deposited, thus: $Na_2S + SrS + 2H_2O = 2NaSH + Sr(OH)_2$, and $Na_2S + BaS + 2H_2O = 2NaSH + Ba(OH)_2$. The mother-liquor is then further boiled down, and on cooling deposits nearly all the strontia or baryta still contained in it. The remaining mother-liquor is practically a solution of sodium sulphydrate, which is treated with carbonic acid, the action being as follows:—$2NaHS + CO_2 + H_2O = Na_2CO_3 + 2H_2S$. The sulphuretted hydrogen given off during the carbonating process is either converted into sulphurous acid or sulphur (depending on the amount of oxygen present) by passing it through a "Claus" kiln.—S. H.

VIII.—GLASS, POTTERY, AND EARTHENWARE.

Composition of Old Ceramic-ware. E. Jensch.
Ber. **19**, 2850—2853.

The author has met with so few published analyses of old ceramic-ware (which occurs in great abundance in Brandenburg), that he has taken the opportunity lately afforded him of analysing pieces chipped from German urns from some of the ancient burying-places. An estimation of the water in them gave the following results:—

	1	2	3	4	5	6
Water, per cent.	1·21	3·46	0·88	2·02	5·29	3·71
	7	**8**	**9**	**10**	**11**	**Mean.**
Water, per cent.	1·53	0·62	1·31	0·79	1·64	1·95

It was also of interest to know what amount of water might exist in chemical combination, the ware having now been exposed to the action of moist earth for so many centuries. The pieces, after being dried at 105°, were raised to a bright red heat, when they lost the following:—

Per Cent.	1	2	3	4	5	6
Loss of weight	2·36	3·17	1·55	8·30	4·23	5·01
Collected H_2O	2·21	—	1·48	8·32	4·17	4·82

Per Cent.	7	8	9	10	11	Mean.
Loss of weight	9·40	1·88	2·42	3·30	2·67	4·02
Collected H_2O	—	—	—	3·11	2·18	3·80

The analysis of these ignited pieces gave the results as shown in table on preceding page. On account of the remarkably high percentage of P_2O_5 in Nos. 7 and 9, this determination was repeated several times with the surprising result, that the phosphoric acid was found to be unequally distributed through the ware.

	a	*b*	*c*	*d*	*e*	
No. 7	·26	·85	·32	·74	·66	Per cent.
No. 9	·41	·12	·97	·30	·36	P_2O_5

An analysis of the clay taken from the same district gave the following:—

SiO_2	62·67
Al_2O_3	29·34
Fe_2O_3 FeO	3·56
CaO	1·17
MgO	0·53
Alkalis	2·02

It may therefore be supposed that the ware was made at the spot where the clay was found.—J. W. L.

An Improved Method of Uniting Metal and Glass. H. H. Lake, London. From B. B. Schneider, New York, U.S.A. Eng. Pat. 3728, March 16, 1886. 8d.

THE union of metal and glass is effected by coating the contact surface of the former with a vitreous enamel or with glass powder fused on, and pressing the two together while in a heated state. By this method it is claimed that glass linings can be fastened in metal cups, metal handles secured to glass vessels, and other similar effects produced.—E. T.

IX.—BUILDING MATERIALS, CLAYS, MORTARS, AND CEMENTS.

Improvements in the Manufacture of Cements or Plasters. C. D. Alison, Camberwell. Eng. Pat. 1126, Jan. 27, 1886. 4d.

THE improved cement consists principally of a non-diatomaceous silicious earth in a finely divided state mixed with various salts of lime, magnesium, sodium, potassium, barium, and zinc. The following mixture gives good results as a fire-proof cement:—Silicious earth 83 per cent., silicate of soda 15 per cent., ground gypsum 2 per cent.—C. C. H.

X.—METALLURGY, Etc.

An Improved Method of, and Means for, Extracting Spelter, and in Apparatus for Treating the Waste Products. W. Tooth, Newington, Sussex. Eng. Pat. 1102, Jan. 25, 1886. 8d.

THE mouth of the fire-clay retort is flanged, and thus fitted air-tight to a front plate by T-headed bolts aided by a lute. To this plate is hinged (horizontally) a conical nozzle, having at its highest point a narrow tubular exit for gases, and at the bottom, which is made level, a plugged tap-hole. In the front is a small cap, removable at will, to facilitate the inspection of the retort during the operation. When coal is employed in the reduction, the hydrocarbon gases may be collected and stored. Calcium carbonate is added to the charge, the proportion depending upon the quantity of alumina and silica present; the residue in the retorts may then be used as a substitute for Portland cement.—W. G. M.

A New or Improved Powder for Hardening Metals. L. A. Groth, London. From C. Beckstein, Reutlingen, Germany. Eng. Pat. 3632, March 15, 1886. 4d.

AFTER extracting the colour from the cochineal insect, 100 parts of the residue are mixed with 212½ parts of phosphoric acid and sufficient nitrogenous organic substance to give 32¼ parts of nitrogen; the mixture is then evaporated, dried and 50 parts of soot added. Sheet-iron may be hardened by heating in contact with this powder in hermetically closed boxes.—W. G. M.

An Improved Basic Lining for Metallurgical Apparatus. A. M. Clark, London. From H. Harmet, St. Etienne, France. Eng. Pat. 3867, March 18, 1886. 6d.

BLOCKS of pure lime, prepared in the usual manner by the calcination of natural limestones, are maintained at a sufficient heat to prevent absorption of water until they can be cut, preferably by means of a band saw, into bricks of the required size. These bricks are either maintained hot or are waterproofed by plunging them into tar or pitch. They must be laid rapidly in position and be backed by a couple of inches of coke and tar mixture, to protect the metallic sheathing from the action of any of the fluid charge which may find its way through cracks in the lining. The furnaces must then be blown in immediately. The old linings, as well as the dust produced by the band saws, may be used as a part of the basic Bessemer lime charge.—W. G. M.

Improvements in the Treatment of Fume in Lead Works. J. Warwick, Newcastle-on-Tyne. Eng. Pat. 12,861, Oct. 9, 1886. 8d.

THE fume is passed through a series of flattened corrugated siphon-pipes, cooled by air or water, on its way to the chimney.—W. G. M.

An Improved Process for Treating and Desilverising Copper Matte and Copper Ores analogous to Copper Matte. H. E. Newton, London. From J. J. and R. Crooke, New York, U.S.A. Eng. Pat. 16,386, Dec. 14, 1886. 8d.

SINCE, in the removal of silver and gold from mattes by fusion over a bath of molten lead, the formation of any lead sulphide interferes with the separation, the inventor proposes to place iron bars beneath the lead but not in contact with any of the matte. The lead is thus desulphurised and the iron sulphide formed rises through the metal bath and unites with the regulus or slag. A reverberatory furnace is employed, having a sloping bottom, with a tap-hole at the upper side for matte, and one on the lower for lead. In the wall of the lower side, at the level of the sole, are several arched recesses communicating with vertical channels in the wall, in which rest the soft iron rods intended for desulphurising. In working the furnace, the lead level must always be above the recesses. If preferred, an already hard lead may be used to extract the first portion of the precious metals with antimony and arsenic, the final treatment being effected with pure lead. The iron bars must be withdrawn during the time that lead is absent from the furnace.

—W. G. M.

XI.—FATS, OILS, AND SOAP MANUFACTURE.

Some Derivatives of Erucic Acid and Brassidic Acid. C. L. Reimer and W. Will. Ber. **19**, 3320—3327.

IN order to obtain erucic acid from rape-seed oil, the authors adopt the following method:—After saponifying the oil with alcoholic potash, the bulk of the alcohol is distilled off and the residue treated with sulphuric acid, when the fatty acids separate. To obtain erucic acid, this mixture of fatty acids is treated with three times its volume of 95% alcohol and the solution cooled to 0°, when the erucic acid separates out in a crystalline form. By one repetition of this process it is obtained chemically pure.

To prepare brassidic acid, it is recommended to heat erucic acid with dilute nitric acid until the former melts (instead of till an evolution of gas commences), and then add sodium nitrite. The formation of oxidation products is thereby avoided. It is not necessary to start from pure erucic acid, for simply by treating the mixture of fatty acids obtained from rape-seed oil in this manner, the brassidic acid is readily obtained, and can be easily purified on account of its slight solubility in alcohol. The derivatives of these two acids described are substitution products in the carboxyl group. Although tri-erucin could not be isolated from rape-seed oil, tri-brassidin can be obtained by treating with nitric acid and sodium nitrite. This body, like the tri-glycerides of palmitic, stearic and myristic acids, possesses a double melting-point. The so-called "stearin" of the oil merchant, a yellow-white substance which separates in the bottom of rape-seed oil barrels after long standing, is di-erucin. This is readily converted into di-brassidin. They are both crystalline bodies. The ethyl-ethers of these acids closely resemble one another, as do their anhydrides obtained by the action of phosphorus tri-chloride. Their amides and anilides are crystalline bodies; the former, when treated with phosphorus pentoxide, appear to yield the corresponding nitriles, but these have not been obtained pure. The ketones of these acids, obtained by the distillation of their respective calcium salts, differ from one another and are both crystalline bodies.—C. A. K.

XII.—PAINTS, VARNISHES, AND RESINS.

Improvements in, or relating to, Enamelling or Coating Wood, Paper, Cloth, Papier-mâché, and other Fibrous or Porous Materials, with Comparatively Impervious Coating or Enamel. W. P. Thompson, Liverpool. From J. A. Pond, Auckland, New Zealand. Eng. Pat. 3572, March 13, 1886. 8d.

THE enamel, which is composed of shellac, is applied, either in the liquid or solid state, to the surface to be coated under great pressure, and at a temperature of 230—300° F. For certain purposes a small percentage of beeswax, stearic, oleic, or any other fatty acid is added. The surface of the material to be enamelled is first varnished with a solution of shellac in methylated spirit.
—E. G. C.

An Improved Composition or Paint for Preventing Attachment of Barnacles to the Bottoms of Iron and Steel-plated Ships. A. C. Ireland and J. R. Bowbeer, Bristol. Eng. Pat. 3636, March 15, 1886. 6d.

THE composition consists of 35% copper sulphate, 40% oxide of iron, 15% pulverised black lead and 10% calcium carbonate, the proportions being varied according to requirement.—E. G. C.

Manufacture of an Elastic Compound in Imitation of Caoutchouc. O. Imray, London. From A. K. Kissel, Frankfort-on-Main, Germany. Eng. Pat. 4918, April 8, 1886. 4d.

ELASTIC compounds have already been made consisting of oil, sulphur and copal, but owing to the expense of copal, could not be used as substitutes for caoutchouc. In this invention the expensive copal is replaced by resin hardened by treatment with caustic lime, etc., as described in Eng. Pat. 8036, 1884. The proportions of the ingredients and temperature employed depend upon the degree of hardness and elasticity required.
—E. G. C.

XIV.—AGRICULTURE, MANURES, Etc.

Chemical Study of Vegetable Albinism: Part III.—Experiments with Quercus rubra. A. H. Church. J. Chem. Soc. (Trans.) 1886, 839—843.

IN two former papers (*J. Chem. Soc.* 1879, 33—41; 1880, 1—6) the author described some conspicuous chemical differences between the white and green foliage of seven distinct plants. The conclusions arrived at from these experiments are now corroborated by comparative analyses of the ordinary foliage and of an albino bough of a forest tree (*Quercus rubra*) in Kew Gardens. The albino leaves are on the average smaller and thinner than the corresponding green ones; the albino bough, its branches and twigs, are of less diameter and length than neighbouring green boughs of corresponding age. The leaves gave on analysis—

	White	Green.
Water	72·69	58·08
Organic Matter	24·65	40·33
Ash	2·66	1·59

The ash of the two sorts of leaf gave on analysis—

		White.	Green.
Ash in dry leaves of *Quercus rubra*		8·33	3·85
100 parts of ash contained—	K_2O	49·38	29·10
	CaO	8·25	21·50
	MgO	6·52	9·55
	Fe_2O_3	0·82	1·24
	Mn_3O_4	2·08	2·36
	P_2O_5	14·25	15·80
	SO_3	7·18	10·05
	Cl	4·25	1·25
	SiO_2	3·15	1·25

These analyses, like those of 1877—79, show the preponderance of potash over lime in the albino foliage, of mineral matter over organic, and the remarkable deficiency of lime. As regards the nitrogen, the results which have been obtained with the scarlet oak are placed side by side with those formerly obtained with *Elæagnus pungens*—

	ELÆAGNUS PUNGENS.		QUERCUS RUBRA.	
	White.	Green.	White.	Green.
Total Nitrogen	4·23	2·82	3·94	2·78
Albuminoid Nitrogen	1·83	1·81	2·65	2·41
Non-albuminoid Nitrogen	2·40	1·01	1·29	0·37

There is no doubt the excessive quantity of non-albuminoid nitrogen contained in the albino foliage is another sign of imperfect elaboration.

Notwithstanding the absence of chlorophyll, and the smaller percentage of total organic matter, the white leaves yield a larger ether extract than the green leaves—5·35 and 5·15% of the dry leaves respectively.

The author's previous conclusion is reaffirmed, that "white leaves are related to green pretty much as immature leaves are to mature, tubers to foliage, petals to green bracts, vegetable parasites to their hosts."
—J. M. H. M.

XV.—SUGAR, GUMS, STARCHES, Etc.

Arabinose. H. Kiliani. Ber. **19**, 3029—3036.

THE author now includes arabinose in his researches on the action of HCN and HI on carbohydrates (*Ber.* **18**, 3066; **19**, 221, 767, 1128, 1914). He obtained the arabinose from cherry-tree gum, as suggested by Bauer (*J. Prakt. Chem.* **30**, 379; **34**, 46). The best results were obtained as follows:—One part cherry-tree gum, in 8 litres of 2 per cent. H SO_4, was heated on the water-bath for 18 hours. The solution was neutralised with hot concentrated $Ba(HO)_2$ solution, concentrated, without previous filtration, to a small volume, and then several volumes 96 per cent. alcohol added, the whole being well shaken. The clear solution was decanted, the greater part of the alcohol distilled off and the residue evaporated to a thin syrup. After again treating with alcohol in like manner the residue crystallised and after removal of the mother-liquor had a pure white colour, and was obtained quite pure by recrystallisation from alcohol. The remainder of the arabinose left in the mother-liquor could be obtained by further purification with alcohol. That the substance thus obtained was really arabinose was proved (1) by the rotatory power $[\alpha]_D = + 105 \cdot 1°$; (2) because nitric acid produced no trace of mucic acid; (3) by oxidation with Br which gave Bauer's arabonic acid. In consequence of several remarkable features of the last reaction, the arabonic acid was studied somewhat more completely. Results generally confirmatory of Bauer's were obtained, but the analytical numbers for the calcium salt agreed best with the formula $(C_5H_9O_6)_2Ca + 5H_2O$. The arabonic acid would, therefore, be a tetrahydroxyvalerianic acid, and although Bauer's analytical data of the free acid do not agree at all with such a compound, the author believes that it was not the free acid but the dehydro acid which Bauer obtained, the analytical numbers agreeing well with such a formula. If these results are correct, arabinose is an α-ketone, which by the action of Br is quantitatively split up into arabonic acid and carbonic or formic acid.

Action of HCN on Arabinose.—One part of arabinose was dissolved on the water-bath in one part of water, and after cooling, an equivalent quantity of 60 per cent. HCN added, the solution being kept in a well-closed flask placed in a vessel of water at the ordinary temperature. After standing 8 days, crystals of the amide of arabinose-carboxylic acid $C_7H_{15}O_7N$ separated. On heating to 130° this amide turns yellow, and at 160° it decomposes with rapid disengagement of gas. In order to prepare the acid itself, the amide was decomposed with baryta water, the Ba precipitated with H_2SO_4 (one or two drops of HCl added keep the solution clear) and the solution concentrated, when, on cooling, colourless shining needles separated. These are easily soluble in water, difficultly soluble in alcohol, and have a neutral reaction. The substance appears to be the dehydro-arabinose-carboxylic acid $C_7H_{12}O_7$, and not the acid itself. It melts at 145—150°, and possesses a rotatory power of $[\alpha]_D = - 54 \cdot 8°$. Although these properties agree closely with those of the dehydrodextrosecarboxylic acid, the crystalline form, which is rhombic, is entirely different, and the action of HI on the arabinosecarboxylic acid produces only a dehydro acid, whereas the dextrosecarboxylic acid produces the normal heptoic acid, thus proving the dissimilarity. The barium and calcium salts were prepared by boiling the dehydro acid with the respective carbonates. They are amorphous, and the analysis of the calcium salt coincided with the formula $(C_7H_{13}O_8)_2Ca$.

—J. W. L.

The Formation and Composition of the Humus Substances. M. Conrad and M. Guthzeit. Ber. **19**, 2844—2850.

THE authors' experiments show that with diluted H_2SO_4, cane sugar is split up, and of the invert sugar as first formed, the levulose is more rapidly decomposed than the dextrose, and that, from the former, ulmin is the principal product, the dextrose producing ulmic acid, which, however, changes to insoluble humin by continued boiling with an acid. They further prove that formic and acetopropionic acids are formed almost exactly in equal molecular proportions. From Tollen's researches it may be inferred that two reactions take place together, producing, besides water, formic and acetopropionic acids on the one hand and humus substances on the other. The authors have, however, as yet, no experimental results to prove this. Another of Sestini's experiments was again carried out—viz., that of heating the humus substances; and the results coincided with his, vapours condensing to a colourless liquid being given off, which reduced silver salts. In the following tables the main results of the experiments are placed together, and require no further explanation than that the humus substances were dried at 110—120° for analysis:—

A.—DECOMPOSITION OF THE SUGARS WITH SULPHURIC ACID.

	Sugar.	Dilute Acid.	Containing H_2SO_4.	Amount of Humus obtained.	Composition of the Humus Substance.

„	10·5	50	4·84	1·77	63·8	4·2
Dextrose	10·5	50	4·78	1·00	64·6	4·2
„	10·5	150	15·0	0·93	65·1	4·6
„	10·5	50	9·6	1·70	—	—
„	10·5	50	17·0	4·15	66·4	4·1
„	10·5	50	22·0	4·50	66·5	4·0

The main results of the research are (1) the amount of humus substances obtained stand in no simple relation to the formic acid, (2) the saccharoses are first inverted before a further decomposition sets in, (3) with the exception of levulose, the carbohydrates produce more humus substances with HCl than with H_2SO_4, (4) the production of humus substances is increased with the concentration of the acid, (5) levulose gives more humus substances than any other carbohydrate. (6) the humus substances contain 62—66 per cent. C., and 3·7—4·6 per cent. H.—J. W. L.

Glycyphyllin, the Sweet Principle of Smilax Glycyphylla. E. H. Rennie. J. Chem. Soc. 1886 (Trans.), 857—865.

FURTHER investigation of this substance shows that it has the formula $C_{21}H_{24}O_9+3H_2O$ when crystallised from aqueous ether, and $C_{21}H_{24}O_9+4\frac{1}{2}H_2O$ when crystallised from water. When boiled with dilute sulphuric acid it undergoes decomposition in accordance with the equation $C_{21}H_{24}O_9+2H_2O=C_{15}H_{14}O_5+C_6H_{14}O_6$, forming *phloretin* and *isodulcite*. Glycyphyllin is, therefore, closely allied to phlorizin. The phloretin was identified by analysis and by the production of phloroglucol and phloretic acid when boiled with strong caustic potash. The isodulcite was identified by analysis and by its crystalline form; assuming that 10cc. Fehling's solution are reduced by 0·0549grm. isodulcite (Will), almost the theoretical percentage of isodulcite demanded by the above equation was produced. The author suggests the possibility that in the decomposition of phlorizin by acids isodulcite is produced, which may have been mistaken by previous observers for glucose. In that case phlorizin would be identical with glycyphyllin. The relation between these two substances is being investigated.—J. M. H. M.

Raffinose or Melitose and its Quantitative Determination. R. Creydt. Ber. **19**, 3115—3119.

IN consequence of a paper by Scheibler on the above subject, (*Ber.* **19**, 2868), the author again publishes a paper which he has already communicated to a sugar trade journal. (See also this Journal, 1886, 386.) It is possible to estimate raffinose by two methods:—(1) By polarisation and inversion, and calculation of the results by the formula given below; and (2) By oxidation with nitric acid, and determination of the amount of mucic acid formed.

(1.) *Method of Inversion.*—When pure cane-sugar or raffinose was inverted with 5cc. of 38 per cent. hydrochloric acid in 100cc. of the sugar solution, the author found that for every 100 scale divisions of Schmidt and Hänsch's half-shade polariscope before inversion, there were obtained after inversion, −32·0 scale-divisions with cane-sugar, and +50·7 with raffinose, the readings being made at 20° C. From these numbers the author obtained the following formulæ:—A = direct reading, B = reading after inversion, C = difference between the readings; then

$$\text{Cane-sugar (per cent.)} \quad \frac{C-0{\cdot}493A}{0{\cdot}827}$$

$$\text{Raffinose (per cent.)} = \frac{A-\text{Cane sugar per cent.}}{1{\cdot}57}$$

These formulæ give good results provided not much already inverted sugars, invert sugar, or dextran, for instance, are present, which influence the results.

(2.) *Oxidation Method.*—A quantity of the substance for analysis, equal to at least 5grms. dry substance, is mixed with 60cc. nitric acid of 1·15 sp. gr., and evaporated on a water-bath to one-third the original volume. The raffinose is thus completely oxidised to mucic acid. The oxidised liquid is mixed with water, and the precipitated acid collected on a tared filter, washed and weighed. Experiments on pure raffinose and mixtures of pure raffinose and cane-sugar, showed that it is possible to determine the sugar within 0·3 per cent. This method is not affected by the presence of invert sugar, etc., since none of these substances yield mucic acid on oxidation. The only known constituent of molasses which gives mucic acid, is Lippmann's levulan, which is rarely present, and then only in small quantity.

Tollens maintains the opinion that the formula of raffinose is $C_{36}H_{64}O_{32}+10H_2O$ (compare this Journal, 1886, 243), and not $C_{12}H_{22}O_{11}+3H_2O$.—G. H. M.

XVI.—BREWING, WINES, SPIRITS, Etc.

New or Improved Aërated Beverages. H. R. Matthews, London, and C. G. Matthews, Burton-on-Trent. Eng. Pat. 3928, March 9, 1886. 4d.

THESE improved beverages are made by mixing wines, spirits or liqueur with water or mineral water in the desired proportions and then bottling and aërating the mixture in the usual way. The advantages gained are constancy of quality and strength and saving of time. —G. H. M.

Improvements in Aërating Brewers' Wort and other Liquids, and in Machinery or Apparatus therefor. F. Faulkner, Oldbury, and W. Adlam, Bristol. Eng. Pat. 4071, March 23, 1886. 11d.

THESE consist in aërating brewers' wort either in the copper, hop-back or cooler—preferably the former—by means of a blast of hot air, in order to render insoluble certain deleterious nitrogenous compounds. The process may also be applied to the "mash-wash" employed in the manufacture of vinegar. The aëration of worts with cold air, whilst undergoing the process of fermentation, is also included in the patent; in this case it is necessary to free the air from germs by filtering it through cotton-wool before blowing it through the fermenting liquid. Full descriptions and illustrations of the plant employed are given in the specification. —G. H. M.

Improvements in Maturing Alcoholic Liquids. W. W. Crawford, Glasgow. Eng. Pat. 4311, March 27, 1886. 6d.

THE maturing is effected by immersing pieces of wood framed together in the casks containing the alcoholic liquid—whisky, for instance. The wood is said to absorb the noxious ethers or essences, and so hasten the maturing of the spirit. This may also be done by applying permeable discs of wood or other material to the cask in such a way that the ethers, etc., rising from the alcoholic liquid, may have access to their under surface, and be able to escape from their outer surface. —G. H. M.

XVII.—CHEMISTRY OF FOODS, SANITARY CHEMISTRY, DISINFECTANTS, Etc.

(*A*) CHEMISTRY OF FOODS.

The Manufacture of Dry Rennet and Process therefor. G. F. Redfern, London. From L. J. Eriksson and E. E. R. Nordling, Upsala, Sweden. Eng. Pat. 11,835, Sept. 17, 1886. 6d.

RENNET BAGS are treated with very dilute hydrochloric acid below a temperature of 40° C.; the extract is then filtered, if necessary, and neutralised with soda lye. To regulate its strength it is tested with milk known to contain both acid and alkali. Suitable gelatinous matter is then added and also some glycerin before drying, to keep it soft and prevent crumbling.—E. T.

(*B*) SANITARY CHEMISTRY.

On the Changes that occur in Suint Waters. A. Buisine. Bull. Soc. Chim. **46**, 497.

THE author finds that the percentage of potassium carbonate in suint varies greatly according to its age, degree of concentration, and so on. Microscopic organisms grow readily in suint waters when left undisturbed, and bring about important chemical changes. A final product of the fermentation, which passes through several stages, is potassium carbonate formed at the expense of the organic salts of the suint. The first change, which may take place in absence of air, is completed in a few days; it is characterised by the formation of potassium salts of carbon and volatile acids, and, simultaneously, urea is converted into ammonium carbonate, and hippuric acid into glycocoll and benzoic acid. In contact with air a second change rapidly occurs, organic substances being completely oxidised to water and carbon dioxide, of which the latter is partially retained by the potash. After this the volatile acids, together with lactic, oxalic and succinic acids, disappear: and lastly, the higher fatty acids and the nitrogenous compounds are decomposed. The benzoic acid appears to remain unaltered. The only gas evolved is carbon dioxide.—S. Y.

An Improved Process for the Softening and Purification of Liquids, and the Construction of Apparatus used therewith. P. A. Maignen, London. Eng. Pat. 2068, Feb. 12, 1886. 8d.

For the purpose of softening water the patentee uses the reagents in the liquid state, and prepares for this purpose "a single solution of the following substances: Quicklime, carbonate or silicate of soda (alum being omitted in this last case), and alum or sulphate of aluminium to suit the character of the liquid to be treated," and finds "when these reagents are mixed together in one solution they do not interfere with one another." After treatment with this solution the turbid water is passed through a "separator;" a vessel which contains shelves packed with spiral wire, sponge, charcoal, wood shavings or other absorbent material.
—C. C. H.

(C) DISINFECTANTS.

An Improved Absorbent and Antiseptic Fabric. T. Roberts, Manchester. Eng. Pat. 1200, Jan. 27, 1886. 4d.

A twilled cotton fabric with a raised or carded surface is rendered antiseptic by treatment with boric acid, carbolic acid and acetate of lead.—C. C. H.

Novel Applications of a Material or Substance produced by the Treatment of Waste Leather. W. Ross, London. Eng. Pat. 9604, July 24, 1886. 6d.

The material consists of the product resulting from the treatment of leather cuttings or waste leather according to the manner described by Newton, Eng. Pat. 1856, 1878. The material (called by the patentee "Calcerine") is to be used as a deodorant or disinfectant. Mixed with stable or similar manure, it absorbs and retains the valuable and volatile emanations. In order to form a liquid manure, calcerine is dissolved in a solution of about one part aqueous ammonia to 99 parts water. The calcerine powder can also be used as an anti-incrustator for steam boilers and for case-hardening iron and steel.—B. H.

An Improved Deodorising Material. J. Watt, South Melbourne, Victoria. Eng. Pat. 15,201, Nov. 22, 1886. 4d.

Spent tan, thoroughly dried and ground to a fine powder, is used for the purpose named. -C. C. H.

For Destroying Bad Smells and Noxious Gases in Sewers, and effectively Ventilating them by the Action of Fire in Flame, or by Heat-producing Substances. G. R. Keeting, Epsom. Eng. Pat. 11,255, Sept. 22, 1885; amended Nov. 24, 1886. 6d.

The apparatus consists of a hollow cast-iron column placed over the mouth of the sewer or drain. In the base is a chamber, fitted with an "atmospheric" gas burner placed under two annular conical cups, which are surmounted with a cap packed with asbestos. The foul air is thus consumed before its passage into the external atmosphere.—C. C. H.

XVIII.—ELECTRO-CHEMISTRY.

Improvements in Electric Batteries. J. Y. Johnson, London. From L. A. W. Desruelles, Paris, France. Eng. Pat. 2631, Feb. 23, 1886. 4d.

To diminish local action, the soluble electrodes are coated with fat or grease (preferably mineral) crushed with mercury, which may contain as amalgam a metal analogous to the soluble electrode.—E. T.

Improvements in the Treatment and Preparation of Materials used in Electric Batteries. J. Y. Johnson, London. From L. A. W. Desruelles, Paris, France. Eng. Pat. 2632, Feb. 23, 1886. 6d.

The partially spent liquids from powerful primary batteries, such as bichromate, according to this invention, are utilised in batteries for working telegraphs and similar purposes, where only a small current but a high E.M.F. are needed. To render these liquids portable, they are mixed with Kieselguhr or other porous or absorbent or acid-proof material, and dried by vaporising the water. When required for use, the addition of water is all that is necessary. The negative electrodes of batteries can be efficiently protected from corrosion by a mixture of grease and mercury.—B. T.

Improvements in Galvanic Batteries. A. Schanschieff, London. Eng. Pat. 2932, March 1, 1886. 6d.

The improved battery has an outer cell made preferably of water-proofed paper. The positive element is zinc, and the negative carbon, the latter being either in the form of a porous vessel or of a flat plate or rod in a porous vessel of some other material, such as earthenware or linen that has been dipped in collodion. Inside the porous vessel is packed peroxide of lead or manganese, mixed with carbon granules. Sometimes an agglomerated block of carbon and peroxide is used as the negative element. Mercury sulphate prepared as in Eng. Pat. 12,378, of 1885, is used as electrolyte. When the peroxide is exhausted, a strong solution of some material, such as chloride of lime (bleaching powder), which is able to restore the peroxide, is used instead of mercury sulphate. Other sulphates than that of mercury may be used but to less advantage.—E. T.

Improvements in Galvanic Batteries. A. Schanschieff and G. R. Fludder, London. Eng. Pat. 3476, March 11, 1886. 8d.

The elements of these batteries are secured to covers of insulating material, one cover serving for several cells. The upper ends of the zincs pass through slots in the cover and are held by pressure between pieces of springy brass bent twice at right angles, and the sides of the slot. The carbons may be secured in the same way or by angle-pieces of metal fastened to them. The cover, and with it the elements, are drawn up by cords wound on a drum fastened to the top of the box, and capable of being turned by hand.—E. T.

Improvements in Voltaic Piles and Accumulators. P. Haddan, London. From J. Crosse, Paris, France. Eng. Pat. 4057, March 23, 1886. 6d.

A diaphragm of cocoanut fibre or compressed powdered cork is saturated with the required chemical fluids and placed between the electrodes of an element in a voltaic battery or accumulator, instead of the exciting liquids as ordinarily used.—B. T.

A Process for Utilising the Spent Liquid from certain Voltaic Batteries. W. S. Squire, London. Eng. Pat. 4522, March 31, 1886. 4d.

The spent liquid of certain batteries in which caustic potash or soda is used, consists of potash or soda combined with oxide of zinc. By means of sulphuretted hydrogen, sulphide of zinc (impure) is precipitated, the caustic potash or soda left in the solution being decanted for use. The impure sulphide of zinc, when treated with sulphuric or hydrochloric acids, yields sulphuretted hydrogen, which may be used as above, and sulphate or chloride of zinc. These may, if desired, be converted into valuable pigments by adding barium sulphide. —E. T.

Certain New and Useful Improvements in Secondary Batteries acting as Accumulators of Electricity. E. Commetin, G. Bailhache, C. Desmazures, A. de Virloy, and L. de Bousignac, Paris, France. Eng. Pat. 7966, June 15, 1886. 6d.

In the improved secondary battery, the positive pole consists of spongy or porous copper plates, or of spongy or porous plates of other metals insoluble in soda or potash. The negative pole consists of brass or other metallic plates wrapped in a gauze of brass wire. These plates are placed horizontally in an aqueous solution of an alkaline salt with a metallic acid or a metallic oxide acting as an acid, such as zincate of soda; some chlorate of soda also is added. The plates and solution are contained in a sheet steel or iron vessel coated with a solution of indiarubber.—B. T.

An Improved Solution or Electrolyte for Primary Electric Batteries. H. Weymersch and J. Whittall, London. Eng. Pat. 9594, July 24, 1886. 6d.

The inventors claim as an efficient solution for any species of primary battery, one containing permanganate of potash, sulphate of potash, sulphate of magnesia, bichromate of soda, sulphuric acid and water in suitable proportions. To obtain a solid compound for transport, etc., chromic acid is substituted for sulphate of magnesia, the proportions being varied.—E. T.

Improvements in or relating to Batteries. A. J. Boult, London. From H. B. Cox, Cincinnati, U.S.A. Eng. Pat. 12,656, Oct. 5, 1886. 4d.

To obtain a primary battery capable of being carelessly handled and even of being inverted without damage, the inventor adds enough gelatine, or other thickening agent, to the battery liquid to bring it to the consistency of a thick jelly.—B. T.

Improvements relating to the Preparation of Metallic Magnesium by Electrolytes, and to Solutions therefor. H. H. Lake, London. From Count R. de Mongelas, Philadelphia, Penn., U.S.A. Eng. Pat. 14,760, Nov. 13, 1886. 4d.

Into a bath made up of concentrated solutions of zinc chloride and magnesium chloride dip an anode of zinc and a cathode of carbon, brass or copper. By passing an electric current through the bath, an alloy of zinc and magnesium is deposited; from this alloy magnesium may be obtained in any known way.—B. T.

Improvements in the Preparation of Organic Matter for Metallisation by Galvanic Deposit. A. J. Boult, London. From "La Société anonyme de Métallisation artistique des Animaux, Vegetaux ou autre Corps, Paris, France." Eng. Pat. 15,403, Nov. 25, 1886. 4d.

A quantity of snails or slugs are washed and placed in distilled water for a sufficient time to allow them to give off their albumen. The albumen is then filtered, boiled for an hour, and about 3 per cent. of silver nitrate added. 30grms. of this liquid are dissolved in 100grms. of distilled water, and the objects to be prepared are submerged in the solution for a few moments; they are next placed in a 20 per cent. solution of silver nitrate and afterwards submitted to the action of "hydrosulphuric gas."—B. T.

Improvements in the Method of, and Apparatus for, Desiccating the Insulating Coverings of Electrical Apparatus. N. J. Raffard, Paris. Eng. Pat. 15,462, Nov. 26, 1886. 6d.

In the improved method of desiccating an electrical conductor, the latter is passed continuously through a vessel containing any substance with which it is to be covered, and thence air-tight through the desiccator proper, which consists of a steam-jacketed vessel, kept exhausted by an air-pump. It then passes through a vessel containing paraffin or other suitable substance. Electrical apparatus is desiccated in a vessel of proper size, warmed in the most suitable and convenient manner, and exhausted by an air-pump. In certain cases the conductors are heated by passing a current of electricity through them while in the vacuum apparatus.—E. T.

Improvements in the Manufacture of Blocks, Plates, or Rods of Carbon for Electrical or other Purposes. H. H. Lake, London. From E. Shaw, Lynn, Mass., U.S.A. Eng. Pat. 15,653, Nov. 30, 1886. 4d.

Seaweed is thoroughly washed by hot water or steam, dried and carbonised; the resulting product is treated with a suitable dilute acid, leaving a pure and very soft carbon, which can be made into various articles by proper machinery. These are claimed to be more suitable, especially for electrical purposes, than those made from any other species of carbon, and to be much less expensive.—E. T.

Improvements in Electric Batteries. H. H. Harris, London. From Count R. de Montgelas, Philadelphia, U.S.A. Eng. Pat. 15,961, Dec. 6, 1886. 6d.

According to this invention, in a galvanic cell a "positive" element of aluminium is used with zinc or any other suitable "negative" element, or a positive element of some material other than aluminium is used with circuit-connections of aluminium.—B. T.

XIX.—PAPER, PASTEBOARD, Etc.

Improvements in the Construction of Boilers for Treating Wood and Other Fibre in the Manufacture of Paper and Other Pulp. J. M. Walton, Glossop. Eng Pat. 16,113, Dec. 9, 1886. 6d.

This invention relates, in the first place, to improvements on an invention made by C. C. Springer, Boston, Mass., U.S.A., Eng. Pat. 8073, July 3, 1885; the object of the present invention being to do away with inside "covering strips," and in the second place to avoid the use of lead-covered bolt heads in the interior of the boiler. The lead lining of the boiler is made in sections of such size and form as to leave an open joint between their edges, which may be packed or left open according to circumstances. Strips of lead or other compressible and acid-resisting material are laid over the joints, these strips being let into each other where the zones cross so as to break joint. These strips are held down by a series of lead-covered cast-iron blocks, which are curved to the form of the inside of the boiler and are laid with their ends touching each other so as to form circumferential rings or zones at right angles to each other or nearly so. These blocks are made thicker at the centre and gradually chamfered off. They are perforated with holes and have a lead covering cast thereon, the lead passing through the perforations and uniting the front and back parts of the covering. Each block is bored in the centre on the side next to the lining, but only extends about two-thirds through the cast iron. This hole is tapped, a corresponding hole being made through lead lining, shell and sheathing of the boiler. The blocks are secured in their places by screw bolts from outside; thus there are neither bolt heads nor nuts inside the boiler.—H. A. R.

XX.—FINE CHEMICALS, ALKALOIDS, ESSENCES AND EXTRACTS.

Synthesis of Active Coniines. A. Ladenburg. Ber. **19**, 2578—2583.

THIS work is an extension of that already published (*Ber.* **19**, 439), the experiments being made on a larger scale and with chemically pure materials.

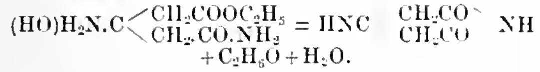
α-Picoline, purified by Lange's method (*Ber.* **18**, 3436), and boiling at 128—129°, was heated for 10 hours to 250—260° with paraldehyde in sealed tubes. The yield of α-allylpyridine was small, but was increased by recovering the α-picoline and heating it again with a fresh quantity of paraldehyde. The product was dissolved in strong acid and distilled with water; the residue was treated with excess of alkali and distilled; a clear watery liquid containing picoline came over first, and then an oil which was collected separately; the bases were separated from the distillates by means of potash, and were dried over potash. By repeated fractionation a quantity of allylpyridine, boiling between 187·5 and 192·5, was obtained. The specific gravity of the base is 0·9595. It is highly refractive, dissolves with difficulty in water, possesses an odour like conyrine, and gives a red colouration with potash. The base and the platinum (double salt) were analysed, and the gold, mercury and cadmium iodide double salts were prepared. That the allylpyridine was an α-compound was proved by converting it into picolinic acid, which melted at 133°. The reduction of α-allylpyridine to α-propylpiperidine was effected by treating the alcoholic solution at the boiling-point with sodium; the yield was almost quantitative and the product pure. The hydrochloride and the base were analysed. The base was found to be chemically and physiologically identical with coniine. The odour of both is the same; the specific gravity of α-propylpiperidine at 0° is 0·8626, and of coniine 0·8625 (*Ber.* **17**, 1679). The platinum and gold double salts, and the cadmium iodide double salts of both bases possess identical properties. As a further confirmation the propylpiperidine was converted ioto conyrine. Crude conyrine, prepared from either coniine or α-propylpiperidine, is fluorescent, but the purified products are not. The platinum double salts are identical in composition and in crystalline form, and melt at the same temperature, 159—160°. The physiological properties of coniine and of α-propylpiperidine were compared by Professor Falck, and were found to be identical. Natural coniine is, however, dextro-rotatory, while propylpiperidine is inactive. An unsuccessful attempt was made to split up the inactive base by the action of penicillium glaucum. It was found, however, that when a crystal of acid coniine dextro-tartrate was placed in a supersaturated solution of acid α-propylpiperidine tartrate, crystals separated slowly; these were removed and purified, and the base was liberated by means of potash. It was found to be optically identical with natural coniine. The mother-liquor was lævo-rotatory, but contained the dextro-rotatory modification. It was treated with cadmium iodide, and the double salt crystallised. The mother-liquor from these crystals was treated with potash to liberate the base, which proved to be nearly pure laevo-rotatory coniine, for it turned the plane of polarisation to the left to the same extent that natural coniine turns it to the right. The author states that this is the first complete synthesis of an alkaloid.—S. Y.

Synthesis of Pyridine Derivatives. H. N. Stokes and H. von Pechmann. Ber. **19**, 2694—2717.

BY the continued action of strong ammonia on ethyl-acetonedicarboxylate at the ordinary temperature, *ethyl-β-hydroxyamidoglutamate* $NH_2COCH_2 - C(OH)(NH_2)-CH_2CO.OC_2H_5$ is readily obtained. Purified by recrystallisation from water, it forms colourless long flat needles, melting at 86°, sparingly soluble in cold water and ether, readily soluble in hot water, alcohol and chloroform. Nitrite of soda added to its solution in hydrochloric acid forms a yellow precipitate of the iso-nitroso compound (?) melting with decomposition at 178°. When one part of ethyl-β-hydroxyamidoglutamate is boiled for about ten minutes with one part of sodium carbonate crystals dissolved in 3—4 parts of water, it is decomposed according to the equation: $C_7H_{14}N_2O_4 = C_5H_6N_2O_2 + C_2H_6O + H_2O$. On acidifying the cold solution with acetic acid, the new compound *glutazine* precipitates as a white powder. It forms colourless rectangular tablets, melting with decomposition at about 300°. It is tolerably soluble in hot water, almost insoluble in hot alcohol, quite insoluble in other solvents. Carbonates are decomposed by it at the boil, forming salts which are, when cold, decomposed in their turn by carbonic acid; it dissolves in cold dilute mineral acids forming the corresponding salts. Its neutral solution gives a deep red colouration with ferric chloride, which changes to dark green on warming. Its sodium, ammonium and barium salts are very soluble in water; these solutions turn green on exposure to the air. By the addition of a slight excess of bromine water to a solution of glutazine in dilute hydrochloric acid, the yellow precipitate which at first forms, is redissolved, and in a short time the liquid becomes filled with colourless crystals of *pentabromacetylacetamide* $CBr_3.CO.CBr_2.CONH_2$. This substance is readily soluble in alcohol, ether, hot benzene and chloroform. When heated with water it is converted into *dibromacetamide*, according to the equation: $CBr_3.CO.CBr_2.CONH_2 + H_2O = CHBr_3 + CO_2 + CHBr_2CONH_2$. With alcoholic ammonia it forms *dibromomalonamide* $NH_2CO.CBr_2CO.NH_2$. Glutazine reacts at 100—120° with acetyl chloride forming *mono-acetylglutazine* $C_5H_5(C_2H_3O)N_2O_2$, which crystallises in small brilliant plates melting at 285—290°. With cold ferric chloride no reaction takes place, but on warming an intense violet colouration is produced; it also does not react with hydroxylamine. Its ammonium salt forms transparent hexagonal plates. Symmetrical *trioxypyridine* [O : O : O : = 1 : 3 : 5] is formed when glutazine is boiled for 3—4 minutes with hydrochloric acid, $C_5H_6N_2O_2 + HCl + H_2O = C_5H_5O_3N + NH_4Cl$. It forms yellowish prisms, is readily soluble in hot water, the solution forming a deep red colouration with ferric chloride, whilst the trioxypyridine of Ost gives an indigo blue colour. Its ammonium salt forms thick prisms; the hydrochloride crystallises in needles. When glutazine or this trioxypyridine is condensed with hydroxylamine, an oxime is formed, probably *diketo-oximidopyridine* [CO : CO : NOH : 1 : 5 : 3], according to the equations: I. $C_5H_5NO_2(NH) + NH_3O = C_5H_5NO_2(NOH) + NH_3$. II. $C_5H_5NO_3 + NH_3O = C_5H_5NO_2(NOH) + H_2O$. This oxime is soluble in hot water, from which it crystallises as a sandy powder consisting of hexagonal tablets; it melts with evolution of gas at 194—196°. On warming its solution in dilute ammonia, a very characteristic intense purple-red colour is produced, one milligramme distinctly colouring several litres of water. Boiling hydrochloric acid regenerates hydroxylamine and trioxypyridine. Phenylhydrazine combines with glutazine, forming the compound $C_5H_5NO_2(N_2HC_6H_5)$. Trioxypyridine, heated with a large excess of ammonium acetate at 120—140°, is readily reconverted into glutazine. Boiling dilute sulphuric acid acts upon glutazine in a different manner to hydrochloric acid, forming instead of trioxypyridine the anhydride of this substance, $C_5H_4NO_2.O.NO_2C_5H_4$. This is a very stable body, slightly soluble in water, insoluble in other solvents, but dissolves in alkaline solutions, forming both acid and neutral salts; it combines also with mineral acids. It reacts neither with hydroxylamine, phenylhydrazine nor with ammonium acetate, but on evaporation of its aqueous solution trioxypyridine is formed.

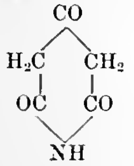
By the action of phosphorous pentachloride on glutazine, four well-characterised products are obtained. I. *Dichlorodioxyamidopyridine* [Cl : Cl : O : O : NH_2 = 2 : 4 : 1 : 5 : 3] crystallises from water in flat needles, melting at 241·5°; is sparingly soluble in hot water and alcohol, readily soluble in alkali and dilute HCl. II. *Trichloroxyamidopyridine* [Cl : Cl : Cl : O : NH_2 = 1 : 2 : 4 : 5 : 3] forms flat needles from alcohol, which melt at 282°. III. *Trichloramidopyridine* [Cl : Cl : Cl : NH_2 = 1 : 2 : 5 : 3] crystallises from water in long delicate needles. It melts at 157·5°, and sublimes without decomposition. IV. *Tetrachloroamidopyridine* [Cl : Cl : Cl : Cl : NH_2 = 1 : 2 : 4 : 5 : 3] forms colourless thin leaflets or almost cubic crystals, melting at 212°, and subliming easily. Hydriodic acid reduces it to pyridine. If this substance is boiled for about two hours with an excess of sodium ethylate and alcohol, *trichlorethoxyamidopyridine* [Cl : Cl : Cl : OC_2H_5 : NH_2 = 1 : 2 : 4 : 5 : 3] is formed, crystallising in colourless needles melting at 83°, and readily volatile with steam : concentrated hydrochloric acid splits it up into ethylchloride and trichloroxyamidopyridine, melting at 282°. But when this substance is heated with sodium ethylate and alcohol to 190°, for 3—4 hours, two new bodies are produced. I. *Dichlorodiethoxyamidopyridine* $C_5N_2H_2Cl_2(OC_2H_5)_2$, forming long needles, melting at 98°, and insoluble in water, acids and alkalis. II. *Dichlorohydroxyethoxyamidopyridine* $C_5N_2H_2Cl_2.OH.(OC_2H_5)$, which forms brittle flat needles, melting at 161·5°, and is soluble in alkalis, forming stable salts.

From the above results it appears that glutazine really is a pyridine compound, and its formation from ethyl-β-hydroxyamidoglutamate may be expressed thus :

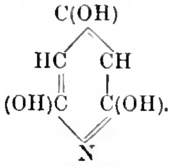


$$(HO)H_2N.C\begin{matrix}\diagup CH_2COOC_2H_5\\ \diagdown CH_2.CO.NH_2\end{matrix} = HNC\begin{matrix}CH_2CO\\ CH_2CO\end{matrix}NH + C_2H_6O + H_2O.$$

Glutazine here appears as the imide of β-imidoglutaric acid. Whether the oxygen atoms are existent in ketone or in hydroxyl form, and whether the nitrogen of the side chain is combined as amide or imide, is still undecided. It, however, may be considered as proved that the nitrogen of the pyridine ring is in the para position to the nitrogen of the side chain and ortho to the two oxygen atoms, and that therefore the above is the symmetrical trioxypyridine. The whole behaviour of this substance has much in common with that of phloroglucinol (1 : 3 : 5 trioxybenzene), which, according to v. Baeyer, seems to exist in two easily interchangeable modifications, as a triketone and as a true phenol. The authors therefore consider that this trioxypyridine does likewise exist in two isomeric modifications, corresponding to the two formulæ :



and



—T. L. B.

Ecgonine. C. E. Merck. Ber. **19**, 3002—3003.

ECGONINE, important on account of its relation to cocaine, has been recently studied by Calmets and Gossin (this Journal, 1885, 509), who found that by distilling it with baryta an oil was first obtained, which latter, by further distillation with baryta, was decomposed into an oil free from nitrogen, ethylamine, and CO_2. The formula of the platinum double salt of the oil first obtained was $(C_8H_{15}NO.HCl)_2PtCl_4$. Merck, who has also subjected ecgonine to a careful distillation with baryta, obtained methylamine, besides some tar and CO_2, the formation of other substances not having been observed. Tropine, subjected to the same process, also gives methylamine. This shows a relation to exist between tropine C_8H_{15}—NO and ecgonine $C_8H_{14}NO.CO_2H$. Merck further studied the action of reducing agents. Fuming HI, as also methyl iodide, heated with ecgonine under pressure and sodium in alcohol, produced no very satisfactory results. ½grm. ecgonine, heated in a closed tube with ½grm. PCl_5 in 5grms. chloroform for six hours, produced, after removal of the phosphorus compounds and chloroform, a crystallisable base, whose gold salt possessed the formula $C_9H_{13}NO_2HCl.AuCl_3$.

—J. W. L.

The Alkaloids of the Berberidaceæ. O. Hesse. Ber. **19**, 3190—3194.

BERBERINE is accompanied by at least four alkaloids in the root of the berberis. If the mother-liquor from berberine hydrochloride is treated with soda, a dark-coloured precipitate of an ether of *oxyacanthine* is thrown down. This, purified by conversion into the sulphate, and precipitation with ammonia, gives the pure alkaloid. The precipitated alkaloid melts at 138—150°, whilst when crystallised from ether or alcohol it has a melting-point of 214°. The amorphous substance is also more soluble in ether and alcohol than the crystalline. The author corrects the formula previously given for oxyacanthine, and now assigns to it the formula $C_{18}H_{19}NO_3$. Its solution in chloroform has the rotatory power $[\alpha]_D$ = +131·6′ (p = 4, t = 15°). It is only slightly soluble in alkalis ; strong nitric acid dissolves it with a brownish-yellow colouration ; with concentrated sulphuric acid or sulphuric acid containing molybdic acid, the solution is colourless but becomes coloured on heating. Oxyacanthine gives good crystallisable salts with acids, which are anhydrous at 100° C.

Oxyacanthine Hydrochloride, $C_{18}H_{19}NO_3.HCl + 2H_2O$, crystallises in small colourless needles, the aqueous solution of which has the rotatory power $[\alpha]_D$ = + 163·6°. Hot strong solutions are coloured green on addition of ferric chloride. It gives a double salt with platinum chloride.

Oxyacanthine Nitrate, $C_{18}H_{19}NO_3.NO_3H + 2H_2O$ crystallises in colourless needles ; the *neutral sulphate* crystallises partly in small prisms containing 6mols. water, and partly in microscopic plates with 2 mols. water. Heated with potassium hydrate and water, oxyacanthine is converted into the potassium compound of β-oxyacanthine ; this latter is easily reconverted into oxyacanthine, and is probably formed by the removal of 1mol. water from the latter. In this respect oxyacanthine behaves like narcotine.

Berbamine, the second alkaloid from berberis, soluble in ether, is thrown down from a solution of its nitrate by ammonia as a crystalline precipitate. It crystallises from alcohol in small plates, which have the formula $C_{18}H_{19}NO_3 + 2H_2O$, and melt at 156°. Its salts are readily soluble in water and are crystallisable. The platinum double salt is a yellow crystalline precipitate, only slightly soluble in water. Dried at 100°, it has the composition $(C_{15}H_{19}NO_3)_2.PtCl_6H_2$.—G. H. M.

XXI.—EXPLOSIVES, MATCHES Etc.

Improvements in Gunpowder for Ballistic Purposes. W. Hope, London. Eng. Pat. 14,914, Nov. 12, 1884. 4d.

THE improvements consist in the substitution of part or the whole of the charcoal in ordinary gunpowder by starch, sugar, flour or other like organic material consisting of carbon combined with oxygen and hydrogen, or bitumen or other like solid hydrocarbon, in order to ensure more perfect combustion.—W. D. B.

Manufacture of Granular Nitro-Cellulose. O. Imray, London. From R. Bernstein, Lind, Germany. Eng. Pat. 12,778, Oct. 24, 1885. 4d.

THIS invention relates to the manufacture of nitrocellulose in the form of fine loose and dense grains. For this purpose the solid fruits, nuts, or shells of nuts produced by various plants of the palm tribe are reduced to powder, boiled in alkaline ley, dried, and nitrated in the ordinary manner. Fragments or waste cuttings of vegetable ivory—the nut of *Phytelephas macrocarpa*—are specially suitable for the purpose. The granular nitrocellulose is very convenient in the celluloid manufacture, may be used in the loose state without being compressed or encased for explosive purposes, and can be thoroughly exploded with a comparatively small detonator.—W. D. B.

Improvements in the Manufacture of Gunpowder. O. Bowen, London. Eng. Pat. 14,052, Nov. 17, 1885. 4d.

THE improvements consist in the employment of the refuse of beech or birchwood for the preparation of charcoal, carbonisation being allowed to proceed only so far as will yield a charcoal of light brown appearance like cocoa.—W. D. B.

An Improved Manufacture of Explosive Compound, and the Preparation of Cartridges therefrom. Sir Francis Bolton, Westminster. Eng. Pat. 1955, Feb. 10, 1886. 6d.

This invention consists in the combination of a solid constituent such as chlorate of potash or other chlorate or nitrate having analogous properties with a liquid constituent such as nitrobenzene or other solvent, in which is dissolved a carbonaceous material such as resin or colophony, molasses, etc. The method of preparing cartridges by filling the solid constituent into bags or cartridge cases and then saturating the same with the liquid constituent, is also claimed.—W. B. D.

Improvements in the Manufacture of Gunpowder. A. H. Durnford, Dartford. Eng. Pat. 3578, March 13, 1886. 4d.

A charcoal very easily inflammable, of low density and only slightly hygroscopic, is prepared by subjecting cork to destructive distillation in suitable cylinders, and the improved gunpowder is prepared by incorporating 20 parts of the charcoal with 80 parts of potassium nitrate. A second variety of the improved gunpowder is prepared by the incorporation of saltpetre, cork charcoal and sulphur, the latter being in the proportion varying from 1 to 10 per cent. The gunpowder is stated to be comparatively smokeless and non-hygroscopic.
—W. D. B.

An Improvement in the Manufacture of Gunpowder. O. Bowen, London; A. S. Tomkins, and J. Cobledick, Surrey. Eng. Pat. 3953, March 13, 1886. 4d.

The inventors prepare a charcoal by the carbonisation of grains of maize and other cereals, and claim its use in the manufacture of gunpowder.—W. D. B.

Improvements in Detonators or Caps to be used with Dynamite or other Explosives. T. Johnston and G. Smith, Glasgow. Eng. Pat. 8368, June 25, 1886. 8d.

This invention relates to improvements in the manufacture of the tubes or shells forming the casing of the detonators or caps employed to start the explosion of charges of dynamite or other explosives, and consists in the longitudinal or transverse corrugation of the shells with a view of increasing the strength of the same, so that the explosive action of the fulminate is concentrated to take effect principally from the inner end and in the direction of the axis of the tube. The detonator tubes may be made of thin steel, and lacquered or otherwise coated to prevent them from rusting.—W. D. B.

Manufacture of an Explosive Compound. H. Imray, London. From H. Dulitz, Duren, Germany. Eng. Pat. 12,838, Aug. 17, 1886. 4d.

An explosive is prepared by the admixture of 20 parts of a jelly consisting of a 5 per cent. solution of gun-cotton in nitrobenzene, and 80 parts of potassium chlorate. Another oxidising agent may be substituted for the chlorate, but the amount so substituted should not exceed 10 per cent., as a larger proportion renders the explosive less sensitive.—W. D. B.

XXII.—GENERAL ANALYTICAL CHEMISTRY.

New Reagent to show the Presence of a Hydroxyl-group. H. A. Landwehr. Ber. **19**, 2726.

As is well known, ferric chloride is a delicate reagent for mono- and di-hydric phenols, and hydroxy-acids. The author has found that bodies belonging to the fatty series, and which contain a hydroxyl-group, also give a colour reaction with very dilute solutions of the reagent. The test is made as follows:—2 drops of a 10 per cent. solution of ferric chloride are diluted to about 60cc. with water; from 10 to 20cc. of this solution are placed in a small porcelain dish, and an excess of the substance to be examined is added. The colour produced is sulphur yellow. All alcohols and carbohydrates which are soluble in water are said to give this reaction. A positive result was obtained in the case of ethyl- and propyl-alcohol, glycerol, grape, cane and milk sugar, erythrite; also glycollic, lactic, tartaric, citric, malic, saccharic and mucic acids. But neither ether, "esters," nor formic, acetic, propionic, butyric, oxalic, fumaric and malonic acids gave the reaction.—T. L. B.

A Test for Stilbene. G. Errera. Gazz. Chim. **1886**, 325.

Bade states that when an alcoholic solution of stilbene is heated with ferric chloride, a red colour is produced. The author shows that this colour is due to the water contained in the alcohol. With anhydrous alcohol the colour is not produced at all, and with aqueous alcohol the depth of colour increases with the amount of water present.—S. Y.

On the Separation of Tin and Antimony by a Volumetric Method. H. Giraud. Bull. Soc. Chim. **46**, 504.

In presence of large excess of hydrochloric acid, antimony pentachloride is completely reduced to trichloride by hydriodic acid, $SbCl_5 + 2HI = SbCl_3 + 2HCl + I_2$; but under similar conditions stannic chloride is not reduced. Tin and antimony are separated from the other metals and converted into chlorides, the solution being made acid enough to keep the antimony in solution without addition of tartaric acid. The perchlorides are formed by warming with potassium chlorate, the excess of chlorine being removed by heating. A certain quantity of the liquid is treated with an equal volume of hydrochloric acid and excess of potassium iodide; the liberated iodine is extracted with carbon bisulphide, which is then washed with water until no longer coloured, the iodine being estimated by titration with sodium thiosulphate. Two atoms of iodine correspond to one atom of antimony. In presence of small quantities of copper the method is not accurate. A strongly acid solution of antimony trichloride is not acted on by iodine, but the iodine is absorbed by stannous chloride. An attempt to estimate tin in presence of antimony by means of this reaction was unsuccessful.—S. Y.

A Direct Separation of Manganese from Iron. L. Blum. Zeits. Anal. Chem. **25**, 519.

A solution containing hydrochloric acid, ferric chloride and manganous chloride is treated with tartaric acid, until on addition of excess of ammonia, no precipitate is formed. The manganese is then precipitated with potassium ferrocyanide; nickel, cobalt and zinc are also thrown down. When filtered cold the filtrate is turbid, but after boiling, a clear filtrate is obtained; the precipitate cannot be washed, hence the reaction is only suitable for qualitative analysis. The author detected the manganese in a solution containing 0·00004grm. of manganese and 0·01grm. of iron in 1cc.
—S. Y.

On the Estimation of Ash by means of Leidenfrost's Drops. T. Salzer. Pharm. C. H. N. F., *1886*, 545.

This method was first suggested by E. Bohlig (*Chem. Zeit.* **10**, 115) for the determination of solid residue in liquids. The author employs it for solid organic substances which melt without decomposition or volatilisation. The substance—for example, oxalic acid—is placed in a platinum basin heated to dull redness; the acid forms a rolling drop which rapidly volatilises and leaves the non-volatile residue in the form of a globule. The drop preserves its shape and motion, even when the evolved gases take fire.—S. Y.

New Books.

Lauber's Handbuch des Zeugdrucks. I. Band: Dritte Auflage. Commissionsverlag von Gustav Weigel, Leipzig. H. Grevel & Co., 33, King Street, Covent Garden, London.

8vo volume, in paper cover; price 6s. Contains 122 pages of subject-matter, Table of Contents and Alphabetical Index, and a few illustrations. The work is divided into chapters—thirteen in number—and treating of the following subjects:—I. Singeing the Goods; Bleaching and Shearing. II. Preparation of Printing Colours. III. Making of the Rollers. IV. Fixing the Colours by Steam. V. Turkey-red Oil, etc. VI. Continuous Soap and Washing Machine. VII. Soaps used in the Printing Processes, &c. VIII. Water in Printworks; Investigation and Purification of Water. IX. Bleaching with Chlorine of the Prepared Goods; Dry Chlorinating and Steam Chlorinating. X. Albumen Colours, etc. XI. Reserves under Albumen Colours. XII. Steam Printing by Decomposition of metallic Salts. XIII. Colours Developed by Decompositions Involving Double Interchange, or the Volatilisation of Acids.

GAS ENGINEERS' POCKET ALMANACK AND LIGHTING TABLE FOR THE YEAR 1887. Issued by William Sugg & Co., Limited, 102, Grand Hotel Buildings, Charing Cross, London, S.W.

SMALL 8VO VOLUME in pocket-book form, bound in morocco leather, gilt, and fastened with elastic band; price 2s 6d. The book commences with a Calendar for 1887; then follows an article on the Lighting and Extinguishing of Street Lamps, etc., which contains a Table giving the Monthly Totals of Lamplight for the yearly totals of 4300, 3940, and 3836 hours. Next appears a useful Diary for Gas Managers, so that between the varieties of coals used in the mixtures for the retorts there can be entered up the makes of gas for each day of the week, the volumes in stock in the holders, and the amounts sent out. A Glossary of terms in frequent use in Gas Works, with their French and German equivalents next follows, and this is followed by the Notification of the Metropolitan Gas Referees as to the times and modes of testing for illuminating power. Well-illustrated descriptions of all the apparatus recommended by the Gas Referees, with reference tables, etc., are added. A Table is given for correcting the volumes of gases for temperature and pressure, etc. Blank pages for memoranda, divided for the months of the year, are arranged; also all the items required to be entered up and summarised each month in a Gas Works are printed and ruled off on alternate double pages, blanks being left only for the figures. The little work concludes with a few useful tables of equivalent weights, measures, and prices, &c., and finally, with some Interpolation Curve Tables, which have been calculated and arranged by Mr James T. Brown. These have the effect of rendering Sugg's Lighting Tables applicable for all parts of the world.

Trade Report.

(From the Board of Trade Journal.)

BOARD OF TRADE NOTICE.

Admission of Samples into Austria-Hungary.

A declaration, between the Governments of Great Britain and Austria-Hungary, was signed in London, on the 15th February last, for the admission duty free into Great Britain and Austria-Hungary of patterns and samples imported by commercial travellers.

TARIFF CHANGES AND CUSTOMS' REGULATIONS.

SWITZERLAND.

Classification of Articles in Customs' Tariff.

(*Note.*—Quintal = 220·4lb. avoirdupois. Franc = $9\frac{6}{10}$d.)

The following decisions affecting the classification of articles in the Swiss Customs' Tariff were given by the Swiss Customs' authorities during the months of December and January last.

"Thomasschlacke," "Thomasphosphate," deposits obtained in the dephosphorisation of iron. Category 3, duty free.

Sumac juice is no longer to be included in Category 16.

Extract of sumac, sumac juice. Category 17, duty 1 franc per quintal.

Grease for leather, in barrels. Category 25, duty 7 francs per quintal.

Phosphate of chalk (artificial manure). Category 4, duty 20 centimes per quintal.

Formic acid. Category 9A, duty 7 francs per quintal.

Chrome acetate, sulphurous acid, antiseptic oil (carbolineum), hypochlorite of potash (Javelle water), and hypochloride of soda (Labarraque water). Category 16, duty 30 centimes per quintal.

Ammoniacal chloride of tin (pink salts). Category 17, duty 1 franc per quintal.

Dregs of indigo. Category 31, duty 4 francs per quintal.

Bronze green, cinnabar green, Russian green. Category 36, duty 3 francs 50 centimes per quintal.

UNITED STATES.

Customs' Decision.

The following decision affecting the classification of articles in the Customs' Tariff, and the application of the Customs' Laws of the United States, was given by the United States Government during the month of January last:

So-called bromo-fluorescic acid, which consists of an aniline colour derived from coal-tar, and principally used in dyeing silk, wool, and cotton fabrics, is dutiable at the rate of 35 per cent. *ad valorem*, under Section 82, for "all coal-tar colours or dyes, by whatever name known," etc.

CAPE OF GOOD HOPE.

Modification in Customs' Regulations.

With reference to the statement that appeared on page 268 of No. 5 of the Journal, a notification has been received from the Agent-General for the Cape of Good Hope to the effect that the following new tariff showing the rebate to be granted, and the Customs' dues to be levied in respect of articles passing overland through the Cape Colony to any of the places or territories which have been proclaimed "free ports" has been substituted for the rates formerly levied, but the regulations under which goods may be so removed and the so-called "free ports" remain unchanged.

EXTRACTS FROM DIPLOMATIC AND CONSULAR REPORTS.

Effect of the Withdrawal of Russian Sugar Bounties.

Sir R. B. D. Morier, Her Majesty's Ambassador at St. Petersburg, in a despatch dated the 10th February last, forwards the following translation of a paragraph which appeared in the *Russian Exchange Gazette* for January 28 (February 9) last, respecting the effect of the withdrawal of the Russian Sugar Bounties on the 1st of July last:—

"Countess M. Branitsky has given orders for the closing of two of her enormous sugar manufactories, the one at Selivonsky, working out annually 250,000 berkovets (one berkovet equals about 360lb. avoirdupois) of beetroot; the other at Kojansky, requiring about 150,000 berkovets. The planters who supplied these works with beetroot have already been informed of this resolution. At the same time, news has been received in Kiev from Smiela, that Count Bobrinsky intends to close two of his sugar manufactories. Hence we see that, owing to the present crisis in the sugar trade, two of our most solid producers are going to cease work. It is evident that they do not wish to stake their last penny on one card, and that those who still mean to struggle on are the very ones that have long been doomed to die, and that conceal the sad state of their affairs."

TRADE NOTICES.

CONSUMPTION OF MINERAL OILS IN RUSSIA.

According to the *Journal de St. Pétersbourg*, of the 14th February last, mineral oils are beginning to be used as fuel on Russian locomotives. The experiment has been made on the Tambow and Saratow Railway, the result being to prove that the inflammable oil is much cheaper than wood. It is now proposed to introduce the former on the principal railways of Southern Russia.

CHILIAN GUANO AND NITRATE OF SODA BEDS.

The following information respecting the guano and nitrate of soda beds in the Chilian province of Tarapacá is extracted from the *Chilian Times* of the 27th November last:—

"The total area of the province of Tarapaca is 16,789½ square miles, and it is divided naturally into five distinct and well-defined zones. The first of these zones commences on the shores of the Pacific, and has an average width, west to east, of 18 miles. It is formed, in the first place, of the beach; and, in the second, of the coast range, which attains an altitude varying from 1125 to 5800 feet above the sea-level. This zone may be denominated the guano and mining zone. The fertiliser is found all along the coast, while the rich mineral fields of Huantajaya and Santa Rosa, and the less important ones of Cármen, Rosario, Huantaca, Paiquina, Chanavaya, and Loa, are situated in the coast sierra. The highest peaks of the sierra Morro de Punta Gorda, 2520 feet; Morro de Pisagua, 3220 feet; Huantaca Hills, 2340 feet; Morro de Tarapacá, 5785 feet; Oyarvide, lat. 20° 31′ 5″, 5800 feet; and Carrazco, 5520 feet. Punta de Lobos sierra has an altitude of 3090 feet, and the banks of the Loa have an elevation of from 1500 to 1600 feet. This belt, as already stated, has an average width of 18 miles, and as it advances eastward it becomes more and more depressed, and finally terminates in a series of pampas (open plains) having an elevation of 3500 to 3800 feet above the sea-level. Nearly all these pampas contain vast beds of salts, sulphate of soda, and sulphate of lime. They are known locally by the name of *salares*. In some parts of the desert of Atacama the beds of nitrate of soda are found under these *salares* deposits, but in Tarapacá the *caliche* (nitrate earth) is found only under a bed of conglomerate known as *costra*. It was believed, at one period, that all the *pampas* in this zone contained *caliche*, but explorations have demonstrated that they only contain traces of nitrate of soda. The true nitrate beds commence on the eastern boundary of the first zone. On the other hand, the hills in the first zone contain copper, silver, and gold, and nickel has been found in the Huantaca Hills. The guano beds, as already stated, are situated in this zone. From Camarones bay to the mouth of the Loa there is hardly a prominence or a rock on the sea-shore that does not contain some guano. This valuable fertiliser has been known from Incarial times. The aborigines of the valleys and gullies of Tarapacá, Mamina, Chiapa, Huatacondo, Camina, and Quisma were acquainted with the fertilising qualities of guano, and they conveyed it from the coast to their farms on the backs of llamas. The southern beds vary so much in aspect and colour that it frequently requires an experienced eye to make them out.

"Many of the deposits are covered with immense layers of sand, whilst others are buried beneath a solid layer of conglomerate or *costra*. Guano is also frequently found in the fissures and gullies which descend to the sea-shore. The Mejillones beds are of small extent, and the guano is of poor quality. The richest and largest beds are at Pabellon de Pica, Punta de Lobos, Huanillos, and Chipana. At the latter place the beds are horizontal and flat. From Chipana to Loa bay there are deposits of guano which have not yet been touched. The second zone of the province is the nitrate region. It commences on the edge of the Camarones gully, and extends southwards to the desert of Atacama. Up to 1858 it was believed that the nitrate beds did not extend southwards beyond the Loa gully, but in that year beds were discovered in what was then the Bolivian littoral. Explorations which were effected in 1872 proved that the nitrate beds extended northwards, beyond the Camarones gully, and that they reached as far as the Chaca gully, and even as far as the Azapa valley, in the province of Arica. The nitrate zone does not run geometrically parallel to the Tamarugal pampa, which is its eastern limit. In some places the grounds run out one or two miles farther to the east, and in some places they bend in that distance from the westward. The quantity and quality of the caliche varies very considerably, but the dimensions of the nitrate zone may be set down at 120 geographical miles in length, north to south, and two geographical miles in width, east to west. It is estimated that the nitrate beds contain the enormous quantity of 1,980,630,502 quintals, and it is stated that, with the present export duty, which is equal to $27\frac{365}{1000}$ pence per quintal, the deposits will yield a revenue of £230,809,171."

RECENT TRADE BLUE BOOKS.

Second Report of the Royal Commissioners on Technical Instruction, Vol V. Foreign Reports, Appendices, etc.

This, the fifth volume of the Second Report of the Royal Commissioners on Technical Instruction, relates chiefly to such instruction in foreign countries. Thus, letters and memoranda are given relating to French Technical Art Schools, Technical Instruction in Italy, Hand-work Instruction in Sweden, Technical Education in Wurtemburg. The programme and course of instruction of many of the principal technical and art schools on the Continent is given; amongst these the chief are the Ecole Polytechnique, Paris, the Ecole des Mines, Paris, the Ecole Commerciale, Lyons, the Ecole Nomale Superieure de Travail Manuel, Paris; the Munich Industrial Art School; Technical High School, Munich (special course for Industrial Chemists). The report contains also many other documents relating to Technical Schools of Instruction both in England, Canada, and foreign countries, the total number which are referred to in the various Appendices being no less than 40. The report, which is dated 1884, was presented on the 22nd of February, 1887."

Erratum.

The President of the Board of Trade has received the following letter from Mr. Neville Lubbock :—

"16, Leadenhall Street, E.C.,
"4th March, 1887.

"MY LORD,

"My attention has been called to the recent issue of the *Board of Trade Journal*, dated February, 1887. In that journal appears a description of the recent reports of the Royal Commission on the Depression of Trade. On the last page (170) is made the following statement :—'A minority report drawn up by the fair trade members of the Commission—viz., Lord Dunraven, Mr. Ecroyd, Mr. Lubbock, and Mr. Muntz, is also appended.' I beg respectfully to point out that it is, I believe, unusual for Departments of State, when alluding to members of Royal Commissions, to classify them by epithets descriptive of the opinions they are supposed to hold. Moreover, I hold that the views put forward in the minority report are in strict accordance with the doctrines of our highest economical authorities on free trade. I do not belong to, and never have been associated with, the Fair Trade League, and I am not even aware, except in a very general way, what principles they advocate. I object therefore to a statement being put forth in the *Board of Trade Journal* which implies that I served on the Royal Commission as a recognised advocate of particular views, and which is, therefore, calculated to mislead its readers. I respectfully request that your Lordship will be good enough to cause this letter to be published in the next number of the *Board of Trade Journal*.

"I have, etc.,
"(Signed) N. LUBBOCK."

[The words "fair trade," of which Mr. Lubbock complains, were inserted by an oversight.]

STATISTICAL TABLES.

FOREIGN TRADE OF INDIA.

Imports and Exports into and from British India.

———	Imports from Foreign Countries.		Exports to Foreign Countries.

THE TRADE OF BRITISH INDIA.

Among the publications recently "presented to Parliament by command of Her Majesty" is a statement of the trade of British India, which bristles with interesting information.

Imports.

The imports of chemicals, drugs, medicines, narcotics, dyeing, and tanning materials amounted to 8,616,601 rupees in 1885-6 against 8,739,470 rupees in 1884-5, a decrease which appears less pronounced than it would have been but for the inclusion in 1885-6, for the first time, of "dynamite and other explosives" under this heading. The import of drugs proper shows a very pronounced falling-off, but that of aniline dyes is growing fast. Some time ago we called attention in these columns to the growing employment of these dyes in the manufacture of Indian fabrics, to the great detriment of the reputation of the latter. Pressure has been brought to bear upon the Indian Government with a view to obtain its aid in discouraging the use of aniline dyes; but so far these representations have been unavailing. Five years ago only three million ounces aniline were brought into India, in 1885-6 nearly 11½ million ounces, and during the first quarter of 1886 alone no less than 4¾ million ounces. The increased consumption of aniline dyes also furnishes a clue to the diminution of the saffron exports from France to India. The imports of mineral oils amounted to 9,611,298 rupees in 1885-6, mostly kerosene, the use of which is becoming quite general. The attempts to find oil in the neighbourhood of Akyab have been abandoned, and it is as yet doubtful whether the oil-bearing region of Beluchistan will render commercial exploitation remunerative. Mineral oil has been brought from Upper Burmah, but it is valuable as a lubricant only.

Borax imports from Thibet into India are diminishing, as the cheapness of the article in Europe renders the carriage of it across the Himalayas unprofitable. Less camphor has also been received from China. Of quinine, India received 11,859 ounces in 1885-6, against 12,261 ounces in 1884-5 and 9936 ounces in 1883-4.

The total value of drugs, medicines, and chemicals imported during these periods was 5,534,070 rupees, 5,481,550 rupees, and 5,081,980 rupees; and of perfumery 557,110 rupees, 662,700 rupees, and 610,120 rupees respectively. The shipments of musk from India were as follows:—1885-6, 3816 ounces; 1884-5, 5759 ounces; 1883-4, 5864 ounces; 1883, 8452 ounces. The average value of the musk exported is put at 32s. per ounce, a convincing proof, if one were needed, that the bulk of it is of very inferior quality.—*Chemist and Druggist*, March 12, 1887.

Exports.

"Chemicals, drugs, medicines, narcotics, dyeing and tanning materials (Class IV.)" is already a sufficiently comprehensive heading in itself, and might, especially in the case of such an important drug-producing country as India, be subdivided with advantage. But when we find dynamite on the one, and tobacco on the other hand, included under its hospitable shelter, the surmise that the Indian authorities look upon this heading as a kind of convenient ash-pit in which to shoot articles unincludable in other classes grows into certainty. This class comprises opium, indigo, cutch, myrobolans, turmeric, cinchona bark, tobacco, and other articles of smaller importance, the aggregate value in 1885-6 amounting to 155,155,727 rupees, a decline of 14 per cent. since 1879-80, mainly accounted for by the diminution of the opium exports. Although still the most valuable item among the merchandise sold to China by India, the trade in opium is falling off seriously. It is to be feared that the cause of this decline must be sought less in a diminished appetite for the drug on the part of the Chinese than in the extension of opium-growing in the Chinese Empire, and the consequent gradual emancipation of that valuable customer. Considering that the opium-tax provides about one-fifth of the total Indian revenue, the decline of the trade is a serious matter to the Government. It may here be mentioned that the imports of salt into India are growing largely. There is a disgracefully heavy duty upon this article also, by which more than one eighth of the Indian revenue is procured.

The shipments of oils are declining, partly because cheaper substitutes have been found for cocoanut-oil as a soap stock, and partly, perhaps, because the depression in trade in Australia restricted the exports of castor-oil, for which that country is a large customer. Gingelly seed is largely purchased by Marseilles, where the oil expressed from it is used for soap-making.

TRADE STATISTICS FOR FEBRUARY.

The Board of Trade Returns for February show the following figures:—

Exports.

	February, 1886.		February, 1887.
Total value	£16,384,007	....	£17,255,133
Foreign and Colonial Produce (partly estimated)	4,916,377	....	5,565,708

Imports.

	February, 1886.		February, 1887.
Total value	£26,621,869	....	£28,513,991

Below are the details affecting drugs and chemicals:—

Exports.

		Feb. 1885.	Feb. 1886.	Feb. 1887.
British and Irish produce:—				
Alkali	cwt.	432,180	431,683	441,411
"	value £	128,060	136,546	125,209
Bleaching materials	cwt.	103,921	109,864	127,944
" "	value £	34,872	41,336	47,709
Drugs and medicinal preparations	"	61,572	59,898	63,321
Oil (seed)	gals.	6,305	5,797	5,759
"	value £	116,074	122,910	119,091
Soap	cwt.	32,918	35,037	38,801
"	value £	37,193	38,765	37,553
Painters' colours and materials (unenumerated)	value £	86,458	96,277	101,393
Foreign and Colonial merchandise:—				
Bark, Cinchona	cwt.	8,336	10,030	17,476
" "	value £	47,216	46,699	76,560
Chemicals (unenumerated)	"	18,978	12,463	12,280
Cochineal	cwt.	965	1,031	653
"	value £	6,793	7,698	4,511
Cutch and gambier	tons	590	773	611
" "	value £	14,741	19,405	15,481
Gum Arabic	cwt.	2,130	2,409	3,852
"	value £	8,009	10,371	17,496
Indigo	cwt.	12,050	10,793	10,008
"	value £	276,668	261,930	229,046
Lac, various kinds	cwt.	5,480	6,708	4,381
" " "	value £	18,765	19,132	12,481
Oils, cocoanut	cwt.	5,551	6,174	3,186
" "	value £	8,843	8,562	4,507

Turpentine	cwt.	23,612	32,734	25,206
"	value £	26,445	45,033	35,383

GERMAN ETHER AND PICRIC ACID EXPORTS.

Last year, 376 tons of ether and collodion were exported by Germany, against 704 tons in 1885. Of this total France was the recipient last year of 158 tons, against only 4 tons in 1885, or an increase of 154 tons. Picric acid was exported during 1886 to the extent of 53 tons, against 23 tons in the previous year, an increase of 20 tons. For January, 1887, the export of ether shows an increase of 18 tons, and that of picric acid about 7½ tons. This increase is mainly due to the development of the export trade with France in these materials, as in January, 23 tons ether and 10 tons picric acid were exported to that country. In January, 1886, no picric acid whatever was sent to France from Germany, and only 627lb. ether.—*Chem and Drug.*, 19th March, 1887.

New Openings for Trade.

Germany—Chemical and Pharmaceutical Commodities.—The British Consul at Dresden, writing at the close of last year, says that the exports of chemical and pharmaceutical commodities look well in the German official returns. Much of the foreign business, like the domestic, he says, gives a very low rate of profit, owing to the enormous fall in the value of chemical, pharmaceutical, and technical products. The overproduction is immense, but the price of some important articles has been kept up by trade coalitions, and the dividends of a certain fraction of the seventy or eighty German companies, though not up to the old level, are fairly satisfactory. As in other branches of manufacture, makers of specialties and holders of patents are obtaining very large returns—*e.g.*, the Berlin Company "Schering" has given 18 per cent., and the shares have lately jumped from 120 to 515. As of particular concern for ourselves, he mentions that the ammonia-soda movement is in active progress, to the detriment, as the German Custom-House statistics show, of the import of British "Leblanc" soda. According to some newspaper figures (which he has been unable to verify) the sales of one great German chemical staple—the chloride of potassium of the Stassfurth Carnallite Works—have been the most extensive effected for some years.

Roumelia—Drugs and Dyes.—Drugs and dyes, we learn from consular reports, are among the articles of first necessity imported into Roumelia from this country. There appears to be good reason to believe that we shall be able to hold our own with these articles.

Turkey—Chemicals, Drugs, &c.—According to the British Consul at Salonica there is a growing demand in Macedonia for chemicals. There has been a sustained demand for drugs, and Austrian imports have accordingly steadily increased. Sulphurous oils and drugs figure among the chief imports from Italy.

Bulgaria—Opening for Toilet Soaps.—There is said to be an opening for toilet soaps in Bulgaria. The Austrians have hitherto done a very good trade by offering cheap imitations of English articles. The bulk of the common soap used is the white Turkish or Cretan, made from olive oil.—*Brit. and Col. Drug.*, 19th March, 1887.

Monthly Patent List.

I.—GENERAL PLANT, APPARATUS, AND MACHINERY.

APPLICATIONS.

1886.

2599 W. Fäger, Liverpool. Improvement in centrifugal machine filters. Complete specification. February 19

2622 W. T. Ramsden and T. Moy, London. Improvements in the method of, and in apparatus for, cooling and freezing. February 19

2654 C. W. Crossley, London. Improvements in the construction, arrangement, and combination of apparatus for the propulsion, suction, and movement of air for ventilating, blowing, and other purposes; applicable also for the movement of fluids and gases. February 21

2678 T. Gautreau, London. Improvements in tubes for steam generators or condensers, and other heating or cooling apparatus. February 21

2710 J. A. Crocker, London. Improvements in filtering machines. Complete specification. February 22

2711 J. A. Crocker, London. Improvements in filtering machines. Complete specification. February 22

2747 J. Gray, Glasgow. Improvements in centrifugal machines for separating fluids of different specific gravity. February 22

2766 J. Y. Johnson—From La Société G. Boone and J. Nory, France. Improvements in decantation apparatus for clarifying and purifying water and other liquids. Complete specification. February 22

2782 H. H. Lake—From W. W. Batchelder, United States. Improvements relating to vapour burners or similar heating apparatus. Complete specification. February 22

2881 B. J. B. Mills—From J. Rétif, France. A new or improved filter for water and other liquids. Complete specification. February 24

2909 A. MacLaine, Belfast. An improved feed-water heater and air extractor in connection with steam engines. February 25

2910 J. C. Thresh, Manchester. Improvements in the manufacture of filtering materials. February 25

2915 J. Critchlow, T. Forester, W. Forester, H. Forester, and L. Forester, Longport. Improvements in filter-presses. February 25

2918. A. T. Winn and W. E. Hainsworth, Dewsbury. Self-acting, self-feeding carbonising and vapour-distributing kiln. February 25

2920 D. Rylands and R. Potter, Barnsley. Improvements in regenerative gas furnaces. February 25

3016 R. R. Evans, London. Improvements in the construction of centrifugal pumps and fans for blast and exhaust purposes. Complete specification. February 26

3023 W. A. Keay, Westerham Hill. Improvements in apparatus for evaporating and condensing liquids. February 26

3024 M. Schwab, London. New or improved apparatus for the intermittent supply of liquid to chemical plant, steam boilers, or other vessels under pressure or otherwise. February 26

3030 F. Weldon, London. Improvements in compressing apparatus. February 26

3045 G. F. Belling, London. High-pressure tap. Feb. 28

3052 R. Hallewell, Manchester. Improvements in the manufacture of water-heating apparatus. February 28

3055 T. Cook and G. Bryant, London. Improved fire-bar for furnaces, etc. February 28

3148 E. Luck, London. Improvements in distillatory apparatus. March 1

3151 A. G. Brookes—From M. Greeven & Co., Germany. Improvements in steam vacuum pumping apparatus. March 1

3210 R. Fraser, Liverpool. Improvements in or appertaining to feed-heating and water-circulating apparatus for steam-boiler furnaces. March 2

3221 H. E. Newton—From E. Theisen, Germany. Improvements in condensing apparatus. March 2

3301 T. Lockerbie, London. Improvements in pipes for conducting liquids, such as acids, alkalis, beer, paraffin oils, and the like. March 4

3364 W. Williams, London. Improvements in fusible plugs for steam boilers, feed-water heaters, and other appliances connected with steam boilers. March 4

3443 E. Wilson, London. Improved disintegrator. Mar. 7

3499 J. P. Jackson, Liverpool. Improvements in apparatus for filtering water and other liquids. March 8

3571 W. P. Thompson—From J. D. Smead. See Class II.

3647 C. H. Roeckner, F. L. Roeckner, and R. L. Roeckner, Tynemouth. Separating solids from liquids; and for filtering liquids. Complete specification. March 10

3701 A. MacLaine, Belfast. Improvements in heating feed-water, and extracting oil and air therefrom, in connection with steam engines. March 11

3729 A. Mayhew, London. A new or improved apparatus for supplying liquid to steam boilers, and other vessels, as and when required, either automatically or otherwise. March 11

3749 M. Kotyra. See Class XVIII.

3793 J. Imray—From La Compagnie Générale pour la Production du Froid Procédes, E. Fixary, France. An improvement in refrigerating apparatus. March 12

3804 J. Howes, Liverpool. Improvements in filtering apparatus. March 14

3839 W. S. Tomkins, London. Improvements in injectors for feeding steam boilers or generators, and raising and forcing liquids for other purposes. March 14

3841 J. Cumming, F. N. Fennell, and G. F. Fennell, London. Improvements in apparatus for heating water or other fluids. March 14

3843 G. Downing—From H. T. Baeschlin, France. Improvements in the manufacture of refrigerating materials. Mar. 14

3848 C. J. Buhring, London. Improvements in and relating to filtering apparatus. March 14

3862 W. A. G. Schönheyder, London. An improved method and apparatus for distilling. March 14

3961 H. J. West, London. Improvements in ice-making and refrigerating machines. March 16

3999 E. Albin, London. Improvements in heating and feeding air to boiler furnaces and the like. March 16

4021 W. P. Thompson, Liverpool—From D. D. Smead, United States. Improvements in apparatus for heating air. March 17

*COMPLETE SPECIFICATIONS ACCEPTED.**

1886.

16,589 E. L. Marsden and P. H. S. Nicklin. Steam blast apparatus. February 26

2864 F. Windhausen. Apparatus for refrigerating. Feb. 26

5669 C. W. Rabitz, London. Filtering apparatus. Feb. 26

6051 J. R. Fothergill. Furnaces for effecting combustion of fuel with air under pressure. March 19

6072 P. A. Maignen. Filtering apparatus. March 16

6282 F. N. Mackay. Apparatus for effecting the absorption of gases by liquids. March 16

6502 A. M. Clark—From M. M. Bair. Construction of furnaces, muffles, and other heating apparatus. March 16

6510 H. J. Worssam and H. Hunt. Preventing the deposit of solid matter in the tubes of apparatus for heating or cooling liquids. March 16

6628 H. E. Newton—From A. L. G. Dehne. Filter presses for use under high pressures. March 19

7202 A. M. Clark—From M. M. Bair. Reverberatory furnaces. March 19

7850 E. G. B. Barlow and C. W. Poole. Apparatus for regulating the supply of compressed gas. March 5

1887.

832 H. J. P. Jolly—From G. Richmond. Method and apparatus for artificial cooling. February 23

1035 H. H. Lake—From V. Collian. Steam generators. Feb. 23

1114 H. J. Allison—From the De la Vergne Refrigerating Machine Company. Buffers for gas compressor valves. February 26

1582 A. J. Boult—From S. W. Merryman. Boiler-cleaning compounds. March 2

2192 H. D. Cooper. Washer especially suitable for the joints of tubes and fittings lined with glass. March 12

2237 H. D. Cooper. Fittings for tubes lined with glass or other material. March 16

---

* The dates given are the dates of the Official Journals in which acceptances of the Complete Specifications are advertised. Complete specifications thus advertised as accepted are open to inspection at the Patent Office immediately, and to opposition within two months of the said dates.

II.—FUEL, GAS, AND LIGHT.

APPLICATIONS.

2623 T. Lishman, London. Improvements in and in apparatus for treating the waste products from the manufacture of gas, coke, and the like. February 19

2674 W. H. Luther and G. Rose, Glasgow. Improvements in and connected with oleaginous vapour or gas and air lamps for lighting and heating purposes. February 21

2708 T. G. Marsh, Lytham. Improvements in gas lighting. February 22

2749 A. J. Boult—From H. W. Brooks, United States. Improvements in the manufacture of steam and oil gas for fuel and for illuminating purposes. Complete specification. February 22

2752 H. J. Siebel, jun., London. Improvements in apparatus for enriching gas. Complete specification. February 22

2870 J. A. Eaton, London—From S. H. Shaw, India. Apparatus for heating air to a high temperature. February 24

2945 G. E. Saville, Manchester. Improvements relating to the manufacture of hydrocarbon gas from coal. February 25

2948 J. Yelland, London. A pot and tank gas furnace combined. February 25

3267 C. W. Watts, London. Improvements in the purification of coal gas, and apparatus therefor. March 3

3271 J. Gilchrist, Glasgow. The burning of solid hydrocarbon (or paraffin wax) in miners' lamps and for keeping the same in a liquid condition, also from being blown out easily. March 3

3291 J. Howard and E T. Bousfield, London. Improvements in the manufacture of gas and in apparatus therefor. March 3

3335 J. Smith and A. Emley, Newcastle-on-Tyne. Improvements in burners for regenerative gas-lighting apparatus. Complete specification. March 4

3367 J. W. Newall, London. Improved method of heating furnaces with liquid fuel. March 5

3388 A. Lentz, Liverpool. Improvements in charging retorts and apparatus therefor. Complete specification. March 5

3396 S. Chandler, jun., and J. Chandler, London. An improved device for checking and regulating the flow of gas. March 5

3418 J. A. Marsh, Cleveland, Ohio, U.S.A. Improvements in apparatus for producing gas or vapour from hydrocarbons, and for utilising such gas or vapour for lighting or heating. Complete specification. March 5

3450 J. J. Lundy, A. G. Christiansen, and F. G. C. Lundy, London. Applications of and improvements in the treatment of the products of combustion. March 7

3571 W. P. Thompson, Liverpool—From J. D. Smead, United States. Improvements in burning liquid fuel, and in apparatus and furnaces therefor. March 9

3617 A. F. Craig, A. Neilson, and J. Snodgrass, Glasgow. Improvements in apparatus for separating mineral or other oils from oils or substances of different specific gravities. March 10

3781 G. E. Darman, Stafford. Improvements in thermopiles relating to those heated and cooled by means of the circulation of liquids. March 12

3978 G. Anderson, London. Improvements in apparatus to be used for the purification of coal gas by ammonia. March 16

COMPLETE SPECIFICATIONS ACCEPTED.

1886.

5522 T. F. V. C. Otto, C. Otto & Co., and The Hibernia and Shamrock Mining Co. Coke ovens. March 5

5858 J. Hepworth and E. Marriott. Removal of ammonia from coal gas, and manufacture of ammoniacal salts therefrom; and apparatus therefor. March 9

5915 W. S. Sutherland. Apparatus for producing heating and illuminating gas. March 2

7733 T. Drake. Manufacturing gas from benzoline or other oil, and apparatus therefor. March 2

8822 M. H. Dement—From G. W. Le Vin. Heating and ventilating apparatus. March 2

8895 H. Williams. Obtaining illuminating and heating gas, and apparatus therefor. March 2

15902 H. H. Lake—From J. J. Johnston. Manufacture of gas for lighting and heating. March 12

III.—DESTRUCTIVE DISTILLATION, TAR PRODUCTS, ETC.

COMPLETE SPECIFICATION ACCEPTED.

1886.

2720 R. J. Lee. Promoting and effecting combustion, especially of medicinal and chemical agents. February 26

IV.—COLOURING MATTERS AND DYES.

APPLICATIONS.

2863 R. H. W. Biggs—From C. M. de Lahorie, Paris. A new or improved method of manufacturing dyes, disinfectants, artificial stone, artificial ivory, and other similar substances. February 21

2985 O. Imray—From The Farbwerke vormals Meister, Lucius and Bruning, Germany. Improved manufacture of a methylene-blue specially adapted for printing on textile fibres. February 25

3028 F. Raschig, London. A process for the production of hydroxylamin. February 26

3039 J. Hickisson (trading as J. Bond & Co.) and A. Layland, London. Improvements in ink for marking linen and other materials. February 26

3280 R. Chadwick and J. Consterdine-Chadwick, London. Improved colouring matter for dyeing, painting, staining, or printing. March 3

3304 R. Reid, Glasgow. Improvements in separating solid matter from alizarin or other colouring matters or starch. March 4

3859 J. W. Lovibond, London. Apparatus for use in estimating, measuring or comparing colour, texture, and appearance of liquid or solid bodies, materials, or fabrics viewed by transmitted or by reflected light. March 14

3991 H. H. Lake—From A. Leonardt & Co, Germany. Improvements in the manufacture of colouring matters. March 16

4036 C. C. Horsley, London. An improved method of, and apparatus for, extracting tannin from bark. March 17

COMPLETE SPECIFICATIONS ACCEPTED.

1886.

5846 J. Y. Johnson—From The Farbenfabriken vormals F. Bayer & Co. Producing a new sulpho-acid, and obtaining azo dyes therefrom. March 2

6000 H. Baum. Production of para-rosanilin and its homologues, and mono-di-tri-alkalised, phenylised, or naphthylised derivatives thereof. March 5

6413 J. H. Johnson—From The Badische Aniline and Soda Fabrik. The preparation from gallic acid of a yellow colouring matter suitable for dyeing and printing. March 16

6631 J. H. Johnson—From The Badische Aniline and Soda Fabrik. Preparing printing colours and solutions of colouring matters suitable for printing and fixing aniline colours on cotton or other similar fibres. March 19

7281 C. A. Martius. Production of azo colours from the paradiamines of stilbene and fluorine. March 19

V.—TEXTILES, COTTON, WOOL, SILK, ETC.

APPLICATIONS.

2695 A. M. Clark—From M. P. E. Gérard, France. An improved process of manufacturing textile threads from viscous or pasty matters. February 21

3662 W. Baxter, Bradford. A machine for finishing and polishing certain textile fabrics. March 10

3715 J. Longmore and W. L. Watson, London. Improvements in the treatment of exogenous plants, flax, jute, rhea, and the like. March 11

3719 P. Parsy, London. Improvements in steeping flax and similar matters. March 11

COMPLETE SPECIFICATIONS ACCEPTED.

1886.

5790 P. Parsy. Steeping flax and other textile matters. February 23

7278 F. Mollet-Fontaino. Treatment of vegetable textile materials, and of threads and fabrics made therefrom. March 9

VI.—DYEING, CALICO PRINTING, PAPER STAINING, AND BLEACHING.

APPLICATIONS.

2811 J. A. Berly—From G. Lombard et Cie., France. Improvements in apparatus for cleansing, bleaching, burling, scalding, and dyeing spun textiles. February 23

3389 F. Towlson and E. Weldon, Manchester. Improvements in dyeing and printing aniline blacks. March 5

3541 W. Walker and J. Drenchfield, London. Improvements in machinery or apparatus for treating fibrous materials and fabrics for bleaching, dyeing, and other analogous purposes. March 8

3561 A. Birch, Manchester. Improved rollers for dyeing, washing, soaping, and bleaching fabrics, etc. March 9

3680 H. E. Ludbrook, London. An improved machine for dressing or separating and cleaning piassava and other vegetable fibres. March 10

3753 J. Burn, Bradford. Improvements in the method of, and apparatus for, dyeing warp and other threads. March 12

VII.—ACIDS, ALKALIS, AND SALTS.

APPLICATIONS.

2561 A. M. Clark—From M. Honigmann, Germany. An improved method for preventing vessels of copper and its alloys being attacked when used for the evaporation of soda and potash leys, and for working soda steam boilers. February 18

2597 R. Fullarton, London. Improvements in means and apparatus for concentration and clarification of sulphuric acid. February 19

2680 A. A. Croll, London. Improvements in the treatment of ammoniacal liquor to obtain salts therefrom, and means or apparatus employed therein. February 21

2762 H. E. Newton—From A. Miller, United States. Improvements relating to the evaporation of salt and other substances in closed vessels. February 22

2963 A. Brin and L. Q. Brin, London. Improvements in the production of chlorine. February 25

2966 J. J. Hood and A. G. Salamon, London. Improvements in the manufacture of sulphate of alumina. February 25

3144 H. L. Pattinson, jun., London. Improvements in the manufacture of hydrates of barium and strontium. March 1

3583 A. A. Croll, London. Improvements in the treatment of sulphate of alumina. March 9

3704 J. Hargreaves, T. Robinson, and J Hargreaves, Liverpool. Improvements in the treatment of cupreous pyrites to separate gold, silver, copper, and sulphur, and to obtain oxide of iron, and in apparatus employed therein. March 11

4002 C. Humfrey. See Class X.

COMPLETE SPECIFICATIONS ACCEPTED.

1886.

4388 T. Capper—From S. Pick. Apparatus used in the manufacture of ammonia soda. March 2

5456 T. T. Mathieson and J. Hawliczek. Purifying black ash, and recovering ammonia therefrom. February 23

5673 J. Hargreaves, T. Robinson, and J. Hargreaves. Treating hydrochloric acid to obtain chlorine, and using the said chlorine in the manufacture of bleaching powder, and apparatus therefor. March 2

5682 J. Hargreaves, T. Robinson, and J. Hargreaves. Manufacture of sulphates of soda and potash, and apparatus therefor. March 2

6468 W. Simon. Manufacture of bichromate of potash. March 2

5681 J. Hargreaves, T. Robinson, and J. Hargreaves. Treating pyrites, and apparatus therefor. March 9

7157 A. M. Clark—From M. Honigmann. Protecting copper vessels used for soda, steam boilers, and for evaporating potash and soda leys. March 16

16491 J. M. Walton. Manufacture of sulphurous acid, and other sulphur compounds, and apparatus therefor. March 16

1887.

1998 A. M. Clark—From J. Brown, F. Herreshoff, W. H. Nichols, and G. H. Nichols. Making pure sulphuric acid and strong sulphuric acid in one continuous operation. March 9

VIII.—GLASS, POTTERY, AND EARTHENWARE.

APPLICATIONS.

2821 W. H. Turner, London. Improvements in or relating to the printing of tiles, and the like. February 23

3205 W. A. O'Sullivan, Dublin. Mechanical glass-bottle blowing. March 2

3258 R. E. Donovan, F. Hazlett, and J. Johnston, Dublin. Improved apparatus for blowing glass by mechanical means. March 3

3431 H. M. Ashley, Ferrybridge. Improvements in the manufacture of bottles and other hollowware in glass, and in the machinery for the same. March 7

3518 A. D. Brogan and A. M. Malloch, Glasgow. An improved method of producing rippled, chequered or other patterns or designs upon rolled plate and sheet glass, and apparatus therefor. March 8

3519 A. D. Brogan and A. M. Malloch, Glasgow. An improved method of producing rippled, chequered or other patterns or designs upon rolled plate and sheet glass, and apparatus therefor. March 8

3671 J. Breeden, London. Improvements in illuminating glass and other transparencies. March 10

3689 W. H. Beck—From La Société F. Benoist et L. Berthiot, France. New or improved machine for surfacing cylindrical and other curved glasses. March 11

3794 T. Garton, London. A novel transparent protective enamel. Complete specification. March 12

3907 T. E. Halford and R. Morant. See Class X.

4005 A. Fielding, Longport. Improvements in the manufacture of artistic pottery. March 17

4062 C. D. Barker and F. C. Hills, London. Improvements in the shape and manufacture of porous pots. March 17

COMPLETE SPECIFICATIONS ACCEPTED.

1886.

5748 W. W. Pilkington. Apparatus for use in the manufacture of plate glass. March 19

6114 R. Young and R. Jex-Long. Manufacture of fire-clay tuyeres, and apparatus therefor. March 5

6150 J. G. Sowerby. Improvement of apparatus used in the fire polishing of glassware. March 9

8559 J. R. Pratt. Potters' lathes. March 16

8957 R. Skeoch and W. G. Wodson. Case kiln for burning bricks and other clay goods. March 2

14979 W. H. Blessley. Manufacture of stoneware. March 19

15009 J. D. Watson. Annealing glass or articles made therefrom. March 5

15552 H. W. Lowden. Tiles for roofing and other purposes. February 23

1887.

178 J. Van de Loo. Presses for the embellishment of ceramic products, and method of applying enamel. March 2

IX.—BUILDING MATERIALS, CLAYS, MORTARS, AND CEMENTS.

APPLICATIONS.

2531 J. W. T. Stephens and R. Clark, Cardiff. The manufacture of Portland, Roman and other cements. February 18

2573 P. Jochum, London. An improved manufacture of blocks or slabs formed of combined argillaceous and ferruginous matter suitable for paving and other purposes, and apparatus therefor, such apparatus being also applicable for mixing pulverulent materials generally. Complete specification. February 18

2863 R. H. W. Biggs—From C. M. de Laborie. See Class IV.

2911 C. S. Lumley and J. Northrop, London. Improvements in the method of paving by the employment of concrete blocks or sets, and in apparatus therefor. February 25

3168 S. Trickett and J. Noad, London. Improvements in the manufacture of hydraulic cements, limes, mortars or concretes. March 1

3507 J. Pope, Folkestone. Improvements in construction of walls of houses, buildings, and the like. March 8

3568 G. G. Girling, Lenham, Kent. Making artificial stone, to be called "Petrean stone." March 9

COMPLETE SPECIFICATIONS ACCEPTED.

1886.

3832 W. E. Constable. Manufacture of artificial ashphalt. February 23

5578 J. D. Gibbins. Method of constructing footways, etc., and producing and laying composition. February 23

5843 C. J. Howe. Manufacture of cement or plaster. March 9

5975 A. J. Boult—From A. Grasset and A. C. Mallat. Manufacture of cement. March 5

6221 C. S. Williams. Construction of fireproof floors. March 2

X.—METALLURGY, MINING, ETC.

APPLICATIONS.

2530 H. Hibbert and W. Horsfield, Nottingham. Improvements in machinery or apparatus used in mines, called "Prop-for Mines." February 18

2541 G. Thew, Farnworth. The prevention of explosions in collieries, named "The Perfect Safety Lamp." February 18

2565 A. M. Clark—From H. A. Brustlein, France. Improvements in the method of cooling ingots, and in moulds therefor. February 18

2602 C. A. Burghardt and W. J. Twining. See Class XVIII.

2681 W. F. Richards and J. Roberts, London. Improvements in the manufacture of iron. February 21

2697 E. Patterson and W. H. Strype, London. Improvements in miners' safety lamps. February 21

2720 J. A. Maskrey, London. Improvements in apparatus for use in the manufacture of tin plates. February 22

2722 J. Banham and S. W. Wilkinson, Sheffield. Improvements in the method of making castings. February 22

2740 M. Constable and J. R. Bingle, London. An improved process for the extraction of gold, silver, and other metals from ferriferous ores containing same. Complete specification. February 22

2774 A. E. Outerbridge, jun., London. Moulds for metal castings. Complete specification. February 22

2780 J. Dahl, London. Improvements in annealing steel. February 22

2834 H. Gardner—From R. J. Henderson, United States. A special treatment of iron ores, and apparatus for that purpose. February 23

2935 J. Dickson, Sheffield. An improved method of preparing steel for roller bars and bed-plate bars used in the manufacture of paper and paper pulp. February 25

2945 E. Robertshaw, London. Improvements in apparatus for preventing accidents in mines or other shafts by overwinding. February 25

2999 L. A. Brode, Glasgow. Improvements in preparing briquettes of ironstone, waste, or dust, or other ferruginous materials for smelting. February 26

3259 J. Ronson, Walsall. Regulating the expansion and contraction of chill rolls, which he calls a "Chill-roll Regulator." March 3

3271 J. Gilchrist. See Class II.

3291 S. Alley and J. A. MacLellan, Glasgow. Improvements in apparatus for making moulds for casting. March 4

3340 J. H. Wicksteed, London. Improved arrangement of shearing machines for cutting hot blooms or cogged ingots. March 4

3356 H. J. Kirkman, London. Improvements in the manufacture of tin and terne plates and galvanised iron sheeta, and other galvanised goods. March 4

3362 J. W. Swan, London. Improved apparatus for the detection of explosive gases in mines or other places. March 4

3109 F. R. Schweizer and C. F. Muhlmann, London. Improvements relating to the casting of metals and alloys. March 5

3115 G. J. Goodhue, London. Timber structures for mines. March 7

3531 T. Shaw, London. Improved method of and apparatus for testing gases drawn from mines, and signalling or indicating the result thereof. March 8

3573 J. L. Parker, Longport. An improved shield for miners' safety lamp. March 9

3669 C. B. Schultze, London. A new or improved process for the extraction and recovery of metals, and especially for the recovery of tin from tinned iron plate. March 10

3670 F. H. Lloyd and H. White, London. Improvements in the manufacture of cast steel, and in apparatus used in the said manufacture. March 10

3696 C. B. Phillips, Chester. The dephosphorating and refining iron, steel, alloys of iron or steel, and other metals and alloys. March 11

3704 J. Hargreaves, T. Robinson, and J. Hargreaves, Liverpool. Treatment of cupreous pyrites to separate gold, silver, copper and sulphur, and to obtain oxide of iron; and in apparatus employed therein. March 11

3738 P. M. Justice—From H. T. Rode, Germany. Improvements in the manufacture of steel and ingot iron. Complete specification. March 11

3741 O. Hehner and T. H. Cobley, London. Improvements in the recovery or extraction of tin, or oxide or salts of tin, from waste tinned iron or tin scrap. March 11

3821 H. W. Martin and J. Turnbull, London. An improved method of damping dust in collieries and mines. March 11

3907 T. E. Halford and R. Morant. An improved method of making glass-lined metal articles. March 15

3974 S. Siemang, London. Compound chilled casting for armour plates. March 16

3975 S. Siemang. Improvements in the manufacture of cast iron. March 16

4002 C. Humfrey, Liverpool. Improvements in or appertaining to the manufacture of sodium. March 17

4006 D. McCorkindale, Mossend. Improvements in preparing malleable iron for making tubes and other articles. March 17

4009 B. E. Clarke, Sheffield. Improvements in miners' safety lamps. March 17

4053 E. Fisher and J. P. Cramp, London. Improved methods of smelting in blast furnaces. March 17

4054 F. Elmore, London. Improvements in the means of and apparatus for the coating of pieces of metal. March 17

4064 J. W. Clewhall and F. Clench, London. Improvements in crushing mills for ore and other materials. March 17

COMPLETE SPECIFICATIONS ACCEPTED.

1886.

2865 F. Bosshardt—From S. Montagne. Method and means for extracting tin from tinned metal cuttings by means of hydrochloric acid gas. February 26

2870 R. Stone. Manufacture of iron and steel. March 2

3393 J Lysaght and J. Lysaght, Limited. Annealing apparatus. March 12

4177 J. W. Wailes. Furnaces and regenerators for production of steel. March 16

4536 W. Penrose and W. Hackney. Manufacture of open hearth steel. February 26

4812 R. Thompson. Implements for breaking down stone or coal. March 2

5681 J. Hargreaves, T. Robinson and J. Hargreaves. Treating pyrites, and apparatus therefor.

6217 A. Johnson. Apparatus for preventing blown-out shots in blasting and tunnelling, and preventing ignition of explosive gas in blasting. March 2

6300 J. M. Bennett. Smelting and refining gold, silver, copper, zinc, lead, and tin ores, and furnaces therefor. March 19.

6180 W. Paterson. Miners' safety lamps. March 2

6550 T. Slater. Manufacture of metallic alloys. March 9

7920 H. Johnson. Apparatus for breaking down minerals. (Previously included in No. 6217.) March 2

16419 W. A. Barlow—From J. Bulliat. Manufacture of fine steel from coarse grain steel, and regeneration of burnt steel. March 9

16523 J. E. Bott, S. J. Hackney and W. Craven. Production of steel for steel castings, and apparatus therefor; applicable also for melting other metals.

1887.

163 H. H. Lake—From W. White. Amalgamating apparatus for separating metals from their ores. March 9

1166 S. B. Stine. Coal-mining machines. February 26

1721 J. Laidler. Safety lamps. March 5

1750 H. H. Lake—From Count R. de Muntgelas. The electrodeposition of aluminium, and apparatus therefor. March 16

1918 A. H. Reed—From H. G. Hicks. Welding compounds. March 9

2117 C. Sheibler. Manufacturing steel and iron, and obtaining by-products therefrom. March 19

XI.—FATS, OILS, AND SOAP MANUFACTURE.

APPLICATIONS.

2615 W. Buttner, J. G. Haller and J. G. Magnus, London. Improved apparatus and means for extracting, washing, and condensing fat, grease, glue, oil or other substances from bones, wool, organic or inorganic substances; for drying the same, and recovering the solvent employed. Complete specification. February 19

2887 C. Wilkins, London. Improvements in marking soap. February 24

2904 D. G. Joy, Kingston-upon-Hull. Improvements in refining oils, fats, and their residues. February 24

3031 A. G. Wass, London. An improved lubricant. February 26

3110 A. Smith, London. A process for deodorising cocoa nut oil. March 5

3592 H. N. Hillman, and G. B. Kleinpass, London. Improvements relating to the manufacture of margarine, oleomargarine, and similar substances. March 9

3617 A. F. Craig, A. Neilson and J. Snodgrass. Improvements in apparatus for separating mineral or other oils from oils or substances of different specific gravities. March 10

3832 A. G. Wass, London. An improved lubricant. Complete specification. March 11

3833 A. G. Wass, London. An improved lubricant. Complete specification. March 11

COMPLETE SPECIFICATIONS ACCEPTED.

1886.

5792 A. J. Boult—From E. Oppelt. Apparatus for extraction of oils or other vegetable juices. March 2

6210 H. W. Langbeck and R. E. Ritsert. Separating cholesterine fats from commercial wool fats, and from lyes of wool-washing works. March 9

1887.

16 R. Wright. Toilet and washing soap. March 12

XII.—PAINTS, VARNISHES, AND RESINS.

APPLICATIONS.

2691 A. M. Clark—From M. P. E. Gerard, France. A new composition capable of being formed into threads, films, sheets, slabs, or moulded articles, or used as a varnish. February 21

3209 W. F. Hurndall, Liverpool. Improvements in paints applicable for painting iron or steel work, the insides and outsides of boilers, and other structures. March 2

3869 W. R. Hutton, E. Fischer, W. Struthers, and T. J. Smillie, Glasgow. Improvements in anti-corrosive or preservative coatings for metallic surfaces. March 15

3987 J. A. Bigsby, Deptford. Improved method of preparing a gummy varnish, coloured or otherwise, for general use or decorative purposes. March 16

4008 W. D. Weissenburg, London. A new way of manufacturing white lead. March 17

COMPLETE SPECIFICATIONS ACCEPTED.

1886.

5820 J. Warwick. Manufacture of white lead. February 23

6370 R. Lavender. Manufacture of oxide of iron pigment. March 12

1887.

2198 W. Dick. Protective varnish. March 19

XIII.—TANNING, LEATHER, GLUE, AND SIZE.

APPLICATIONS.

3027 E. Tuteur and W. J. Goulborne, London. Improvements in leather compositions applicable to various useful purposes. February 28

3623 J. Pickup, E. Pickup, and J. Pickup, Manchester. Improvements in apparatus for boiling size in size boxes of sizing machines; applicable also to other machines or apparatus where an injection of steam is used to obtain boiling. Complete specification. March 10

3860 H. Golding, London. Improvements in treating leather. March 14

COMPLETE SPECIFICATIONS ACCEPTED.

1886.

13283 A. M. Clark—From J. B. West. Tanning and stuffing leather. March 16

1887.

1163 J. H. G. Langenhagen. Dressing for leather. Feb. 26

XIV.—AGRICULTURE, MANURES, Etc.

APPLICATIONS.

3088 H. Stevenson and J. T. Hazeldine, London. The manufacture or making improved artificial manures. February 28

3179 J. Hardwick and J. R. Shearer, London. Improvements in the manufacture of hygienic manure by the treatment of excreta and sewage, and in the methods of its application to land and plants; suitable also as a destroyer of noxious insects, aa a disinfectant, and for other purposes. March 2

3292 T. McMurray, Glasgow. New or improved compounds to be used for deodorising, filtering, and manuring purposes. March 4

COMPLETE SPECIFICATION ACCEPTED.

1886.

6732 T. H. Cobley. Treatment of sewage sludge, and preparation of a manure therefrom. March 19

XV.—SUGAR, GUMS, STARCHES, Etc.

APPLICATIONS.

2572 C. D. Abel—From T. Roussélot, The Antilles. Improvements in multiple three-roll sugar-cane mills. February 18

2905 H. H. Lake—From La Compagnie de Fives-Lille, France. Improvements relating to diffusing apparatus for use in the treatment of beetroot, sugar-cane, and other substances. February 24

2983 G. F. Marshall, London. The manufacture of an improved carbon for filtering and decolourising purposes. February 25

3526 A. E. Major, Wandsworth. Improvements in the manufacture of sugar. March 8

COMPLETE SPECIFICATIONS ACCEPTED.

1886.

5562 T. M. Aitken and J. McNeil. Machines for cutting sugar canes. February 23

5792 A. J. Boult—From E. Oppelt. See Class XI.

1887.

1931 M. A. Perret. Apparatus for extracting the saccharine or other soluble matter from sugar cane, etc. March 19

2138 H. L. Sulman and E. E. Berry. Treatment of grain for the manufacture of starch or glucose. March 19

XVI.—BREWING, WINES, and SPIRITS.

APPLICATIONS.

2936 G. Epstein, London. Improvements in the treatment of brewers' and distillers' grain. February 25

3187 J. Klein, London. Improvements in apparatus for filtering beer and other liquids. March 2

3240 G. Epstein, London. Improvements in the treatment of coffee, porter, and other drinks, and apparatus therefor. March 3

4013 C. Lesne, London. The cure of musty and otherwise stinking brewers' casks. March 17

COMPLETE SPECIFICATIONS ACCEPTED.

1886.

4168 W. Spencer and J. Jones. Treatment of brewers' wort. March 16

5457 W. S. Squire. Manufacture of yeast. February 23

5772 F. Faulkner and W. Adlam. Treating brewers' wort. March 2

6112 G. F. Redfern—From P. Lauth. Apparatus for drying and germinating barley, etc. March 9

6401 H. Schaarwachter. Apparatus for pasteurising beer, wine, etc. March 5

8420 A. Boake and F. G. A. Roberts. Application of an improved antiseptic salt in brewing. March 5

XVII.—CHEMISTRY OF FOODS, SANITARY CHEMISTRY, DISINFECTANTS, Etc.

APPLICATIONS.

A.—Chemistry of Foods.

1886.

17165 C. A. Wahlin, A. Forssell, and F. L. Enguist, London—From A. T. Pfeiff, Sweden. Improvements in the treatment of milk. August 19, 1886. Received 18th February, 1887, and ante-dated under International Convention.

1887.

2937 G. Epstein, London. Improvements in the treatment of coffee, and apparatus therefor. February 25

3128 G. Grout and G. Shenton, London. An improved addition to farinaceous substances for making bread, biscuits, cakes, and other articles of food usually made therefrom. March 1

3284 C. A. Sahlstrom, Aberdeen. Improvements in preserving, and apparatus for the same. March 3

3461 G. Bischof, London. A process of, and apparatus for, purifying water. March 7

3471 H. Kochert, London. Improved preserved food. March 7

3597 T. Rickett, Southampton. Improvements in the process of bread raising and baking in ovens. Complete specification. March 9

4063 W. L. Wise—From C. A. Wahlin, A. Forssell, and F. L. Enguist, Sweden. Improvements in the treatment of milk. March 17

B.—Sanitary Chemistry.

2553 A. Angell, London. Improvements in the manufacture of precipitants, and in the treatment of sewage. February 18

2860 H. Davey, Leeds. A method of automatically raising sewage. Complete specification. February 24

3179 J. Hardwick and J. R. Shearer. See Class XIV.

3292 T. McMurray, Glasgow. New or improved compounds to be used for deodorising, filtering, and manuring purposes. March 4

3338 E. Crutchloe, London. Improvements in furnaces for securing the complete reduction of any organic matter to ashes, and rendering innocuous and inoffensive the gases escaping therefrom. March 4

3352 G. Gehring, London. Process and apparatus for the separation and disinfection of fœcal and other matters, March 4

C.—Disinfectants.

2831 J. H. Harford and W. W. Reeves, London. An improved disinfecting and curative device, and composition or powder to be used therewith. February 23

2863 R. H. W. Biggs—From C. M. de Lahoric. See Class IV.

COMPLETE SPECIFICATIONS ACCEPTED.

A.—Chemistry of Foods.

1886.

4114 A. S. Krueger. A preparation for a new beverage similar to coffee. February 23

9518 C. Millen. Preparation and preservation of cocoanuts for use as food. March 16

17087 A. B. Imrie. Refrigerating machinery applicable to freezing machines for preserving meat and other perishable substances. March 19

1887.

1996 J. Carnrick. Process and apparatus for manufacture of powdered milk. March 9

B.—Sanitary Chemistry.

1886.

3973 J. W. Slater, S. K. Page, W. Stevens, and the Native Guano Company, Limited. Preparation of materials for use in the treatment of sewage and foul water. February 23

4203 L. G. G. Daudenart. Purification and utilisation of sewage, and apparatus. March 9

6732 T. H. Cobley. See Class XIV.

13829 F. Candy. Manufacture of materials for use in the treatment of sewage, to effect the separation of matters in suspension and solution in the water thereof, and the clarification and purification of other polluted water, and certain other liquids. March 19

1887.

278 J. Wohanka and K. Kocian. Purification of sewage. March 9

C.—Disinfectants.

1886.

6191 W. D. Borland. Manufacture of bromine preparations for sanitary purposes. March 9

6966 H. M. Caldwell. Improved deodorant and disinfectant. March 16

11011 J. W. Knights and W. D. Gall. Disinfecting powder. March 12

XVIII.—ELECTRO-CHEMISTRY.

APPLICATIONS.

2588 L. Hanson, Halifax. An improved construction of armature for dynamos or electric motors. February 19

XIX.—PAPER, PASTEBOARD, Etc.

APPLICATIONS.

3029 J. B. Spence, London. Improved mode of preparing fibres for use in paper making and other purposes. Feb. 26

3100 P. Cook, Glasgow. Improvements in and connected with the manufacture of papier-mâché hollow vessels, and in mechanism therefor. February 28

3122 H. J. Shawcross and B. H. Thwaite, Liverpool. Improvements in the method of manufacture and subsequent treatment of paper-tissue fabrics, wood, and like material for the production of writings, prints, designs, or other impressions in ink black and in colours. March 1

3891 T. Worth, Droylsden. An improvement in the waterproofing of paper for packing and other purposes. March 15

3927 C. Russell and P. H. Craigin, London. Improvements in paper-pulp screens. Complete specification. March 15

3937 A. Wilkinson, London. The treatment of fibres for pulp, and the manufacture of paper therefrom. March 15

COMPLETE SPECIFICATIONS ACCEPTED.

1886.

1076 A. Schlumberger. Manufacture of cheques and other papers so as to prevent fraudulent alterations therein. Feb. 26

5563 W. E. Heys—From E. G. H. Ladewig. Manufacture of fire- and waterproof paper, millboard, etc. March 2

6585 J. G. Dunbar and A. Mackenzie. Apparatus for regulating the supply of pulp to paper-making machines. March 9

1887.

517 H. H. Lake—From E. R. Wiggin. Manufacture of corrugated paper and similar fabrics. March 2

523 H. H. Lake—From E. R. Wiggin. Machinery for use in the manufacture of corrugated paper. March 2

1443 R. Eisentraut. Manufacturing composition from cellulose or ground wood, which can be moulded by heat and pressure. March 2

1808 H. H. Lake—F. J. Marshall. Machinery for the manuacture of paper pulp. March 5.

XX.—FINE CHEMICALS, ALKALOIDS, ESSENCES, AND EXTRACTS.

APPLICATION.

3678 S. H. Levi, London. A process of treating the seeds of the fruit of a certain tree to render the same fit for industrial or commercial purposes. March 10.

COMPLETE SPECIFICATIONS ACCEPTED.

1886.

5936 E. Edwards—From E. A. Viteau. Process for complete purification of perfumes, in the manufacture of which sulphuret of carbon has been used. March 2

6259 C. D. Abel—From La Société Anonyme des Parfums Naturels de Caones. Extraction of perfume essences. Mar. 9

XXI.—EXPLOSIVES, MATCHES, Etc.

APPLICATIONS.

2628 H. S. Maxim, London. Improvements relating to the manufacture and treatment of dynamite, blasting gelatine, and similar explosive compounds, and to apparatus therefor. February 19

2679 C. Roth, London. Improvements in the manufacture of explosives. Complete specification. February 21

3173 S. H. Nealy and L. Hutchins, London. Improvements in marine torpedoes. Complete specification. March 1

3245 H. Jephson, Derby. Improved fog-signal detonator. March 2

3176 E. L. Sheldon, London. An improved match or cigarette light. March 7

3550 J. P. Gibbins, London. A land mine or torpedo for the discharge of grenades, small shell, or other missiles, over a large area. Complete specification. March 8

3551 J. P. Gibbins, London. A floating electro contact or automatic mine. Complete specification. March 8

3554 J. Fraser, London. Improvements in the method of, and apparatus for, manufacturing lucifer matches. March 8

3675 A. V. Newton—From A. Nobel, France. Improvements in explosive compounds. March 10

3676 A. V. Newton—From A. Nobel. Improvements in detonators. March 10

3778 W. W. Walker and E. A. McAdam, Liverpool. Improvements in matches, wax-vestas, tapers, and the like. March 12

3872 E. St. John Christophers and B. Dunk. The improvement of explosive shells. March 15

3887 G. P. Lemprière, Birmingham. Improvements in exploders or detonators for fog signals, torpedoes, artillery, fire-arms, blasting cartridges, and other articles of a like nature. March 15

3920 A. J. Boult—From L. Bagger, United States. Improvements in, or relating to, the igniting of explosive charges. Complete specification. March 15

COMPLETE SPECIFICATIONS ACCEPTED.

1886.

4525 G. A. Sweetser. Improvements in the manufacture of cigar lights, fusees, or vesuvians, and apparatus therefor. March 2

6258 C. D. Abel—From F. Gaens. Explosive compound for blasting. March 5

5494 H. von Schenk. Manufacture of substances for igniting matches. March 16

NOTICES.

In accordance with the provisions of Rule 18 of the Bye-laws, notice is hereby given that those members of Council whose names are placed in italics in the annexed list, will retire from their respective offices at the forthcoming Annual General Meeting.

Professor James Dewar, F.R.S., has been nominated to the office of President, and Mr. David Howard has been nominated Vice-President under Rule 11.

Professor Clowes, Mr. J. Neilson Cuthbertson, Mr. Ivan Levinstein, and Professor W. A. Tilden, F.R.S., have been nominated Vice-Presidents under Rule 8; and Mr. B. S. Proctor has been nominated Ordinary Member of Council under Rule 17, in the place of Mr. Levinstein, nominated Vice-President.

The Treasurer and Foreign Secretary have been nominated for re-election.

Members are hereby invited to nominate fit and proper persons to fill four vacancies among the Ordinary Members of Council under Rule 18. Special nomination forms for this purpose can be obtained from the General Secretary upon application.

Extract from Rule 18:—"No such nomination shall be valid, unless it be signed by at least ten members of the Society, who are not in arrear with their subscriptions, nor unless it be received by the General Secretary, at the Society's Office, at least one month before the date of the commencement of the Annual General Meeting, to the election to take place at which it refers. Nor shall any such nomination be valid if the person nominated be ineligible for election under Rules 12 or 15. No member shall sign more than one nomination form."

Notice is hereby given, that the next Annual General Meeting will be held in Manchester on Wednesday, Thursday, and Friday, the 13th, 14th, and 15th of July next. Detailed arrangements and the programme of proceedings will appear as soon as complete.

The supply of copies of the Journal for January, 1882, and January, 1883, being now exhausted, the Secretary would be glad to receive communications from members possessing extra copies of those numbers, in good condition, with a view to purchase.

Should sufficient applications for complete sets be received, the numbers will be reprinted.

Authors of communications read before the Society or any of its Local Sections are requested to take notice that, under Bye-Law 43, they cannot receive the prescribed 50 copies of their communications unless they comply with the condition laid down in that Bye-Law—viz., that they give notice of their desire to receive such copies upon their manuscript before sending it to the Editor. Mention should also be made as to whether the Discussion is to be included in the reprint.

CHANGES OF ADDRESS.

W. B. Allbright, l/o Dorchester; c/o Halstead & Co., 196–202, Forsyth Street, New York, U.S.A.

J. Barrow, l/o Eccles; Beech House, Folly Lane, Swinton, near Manchester.

H. Brunner, l/o Widnes; Holly Mount, Tarbock Road, Huyton, near Liverpool.

L. C. Daniell, l/o London; Toohey's Brewery, Sydney, New South Wales.

J. F. Davis, l/o New York; 551, Quincey Street, Brooklyn, New York, U.S.A.

D. B. Dott, l/o Abbey Hill; 24, Castle Street, Edinburgh.

A. H. Elliott, l/o Columbia College; office of "Anthony's Bulletin," 59, Broadway, New York, U.S.A.

G. E. R. Ellis, l/o Bayswater; The County College, Hereford.

N. Farrant, l/o St. Paul's Road; 2, Lawnside, Bearwood Road, Smethwick, Birmingham.

A. C. Fryer, l/o Richmond Hill; Cornwallis Lodge, Clifton, Bristol.

G. J. Hamlen, l/o Hull; 9, Muir Street, Silvertown, E.

C. M. King, l/o 5; 63, Ferme Park Road, Hornsey, N.

A. H. Mason; Journals, etc., to P.O., Box 1979, Montreal, Canada.

D. Melville, l/o Boston; North Woburn, Mass., U.S.A.

J. Merrylees, l/o Rio Tinto; c/o Cassel Gold Extracting Co., Limited, 13, West Scotland Street, Kinning Park, Glasgow.

J. A. Morrice, l/o Pollokshields; 1, Athole Gardens Place, Kelvinside, Glasgow.

Jas. Muter, l/o Fauldhouse; c/o Finlay, Fleming & Co., Rangoon, Burmah.

W. H. North, l/o Manningham; Ingleby Street Dyeworks, Browroyd, Bradford, Yorks.

Jas. Park; Journals, etc., c/o Stevenson, Carlisle & Co., Milburn Chemical Works, Garngad Hill, Glasgow.

H. A. Rademacher, l/o Charlestown; Cellulose Factory, Glossop.

F. W. Richardson, l/o Whetley Grove; 2, Farcliffe Place, Bradford, Yorks.

W. Johnston Saint, l/o Munich; 11, Queen's Road, Aberdeen.

Wm. Scott, l/o Ardgowan Street; 2, Robertson Street, Greenock, N.B.

C. A. Serre, l/o Fulton Street; 862, Broadway, New York, U.S.A.

Fred. Smith, l/o Sutton-on-Hull; c/o New Explosives Co., Limited, Stowmarket.

J. Johnston Smith, l/o Port Glasgow; Castle Brewery, Newark-on-Trent.

Thos. Steel, l/o Fiji; Yarraville Sugar Refinery, Melbourne, Victoria.

D. Stewart, l/o Kirkintilloch; 152, Birkbeck Road, Tottenham, N.

F. P. Stiker, l/o Ellicott Street, 206, High Street, Buffalo, New York, U.S.A.

E. Sykes, l/o Nursery Street; 14, Edmond Street, Seedley, Pendleton, Lancashire.

G. Crosland Taylor, l/o Neston; Riverside, Boughton, Chester.

G. G. Tomlinson, l/o Rainham; 10, Maude Grove, West Brompton, S.W.

Jas. Towns, l/o Victoria Docks; 50, Morgan Street, Canning Town, E.

A. W. Warrington, l/o Göttingen; 1, Grafton Square, Clapham, S.W.

CHANGES OF ADDRESS REQUIRED.

W. F. Jack, l/o Ravensworth, Neath, Glamorganshire.
J. Lawrence, l/o 7, Bellgrove Terrace, Glasgow.
R. Wightwick Roberts, l/o Valparaiso, Chili.

LIST OF MEMBERS ELECTED, 22nd APRIL, 1887.

Jas. Armour, c/o Clippens Oil Co., 16, Bothwell Street, Glasgow, clerk.

T. F. Barbour, Chemical Laboratory, University of Edinburgh, assistant.

Alex. Barr, 42, Bath Street, Glasgow, asphalte and waterproof cloth manufacturer.

R. Bloomfield, Thurma Factory, viâ Darbhunga, Tirhoot, India, indigo planter.

Thos. Fletcher, 99, Great Hampton Street, Birmingham, master baker.

Jas. Hardman, Whitwood Chemical Works, Normanton, manager.

Jno. Harrison, 35th and Gray's Ferry Road, Philadelphia, Pa., U.S.A., chemical manufacturer.

A. Frederick Jones, 15, Dawson Place, Bayswater, W., sodium nitrate manufacturer.

J. West Knights, County Laboratory, Cambridge, public analyst.

Alex. L. Lineff, 12, Buckingham Street, Adelphi, W.C., consulting engineer.

Harvey M. Mansfield, Fairfield, Somerset Co., Maine, U.S.A., chemist to Wood Fibre Company.

Frank Moul, Aldersgate Chemical Works, Southball, chemist.

Thos. C. Palmer, 121, Adelaide Road, Haverstock Hill, N.W., engineer.

E. Cheshire Patchitt, 128, Derby Road, Nottingham.

Dr. W. H. Perkin, jun., 33, Central Road, Withington, Manchester, chemist.

Chas. E. Pickard, Phœnix, Oswego Co., New York, U.S.A., student in applied chemistry.

Herb. Pilkington, Tipton Green Furnaces, South Staffordshire, blast furnace manager.

Edw. Ramsden, Holly Bank, Great Horton, Bradford, Yorks., spinner.

Alex. J. J. Ross, Battlefield Cottage, Falkirk, N.B., chemist.

C. J. Thompson, 11, Bentley Road, Prince's Park, Liverpool, pharmacist and analyst.

Jas. Totton, 150, Shaw Heath, Stockport, chemist.

Death.

E. Addenbrooke, 18, Cawley Road, South Hackney, E.

London Section.

CHEMICAL SOCIETY'S ROOMS, BURLINGTON HOUSE.

Chairman: David Howard.

Committee:

Sir F. A. Abel.
H. E. Armstrong.
W. Lant Carpenter.
W. Crowder.
C. Graham.
S. Hall.
A. K. Huntington.
R. Messel.
B. E. R. Newlands.
B. Redwood.
T. Royle.
John Spiller.
G. C. Trewby.
J. Williams.

Hon. Local Sec. and Treasurer: Thos. Tyrer, Garden Wharf, Church Road, Battersea, S.W.

The meetings of the London Section will be held on the first Monday in each month.

SESSION 1886–87.

Prospective Arrangements.

May 2.—Dr. P. F. Frankland, "Recent Bacteriological Research in connection with Water Supply."
,, Dr. C. R. A. Wright, "The Action of Zinc Chloride on Castor Oil."
,, 16.—Messrs. Cross & Bevan, "Pictet's Wood Pulp System."
,, Mr. John Ruffle, "The Estimation of Moisture in Superphosphates and similar Fertilisers."
June 6.—Dr. H. E. Armstrong, "The Alkaloids—the Present State of Knowledge concerning them, and the Method employed in their Investigation."
,, Mr. Boverton Redwood, "Notes of a Recent Visit to some of the Petroleum-producing Territories of the United States and Canada."
July.—Annual Meeting in Manchester.

Notices of Meetings and Papers will be found in the Scientific Journals.

Notices of papers and communications to be made to the Local Secretary.

Meeting held April 4, 1887.

THE PRESIDENT IN THE CHAIR.

THE Triennial Election of Officers and Committee of the Section was made. Thanks to the Chairman and Committee were proposed and replied to by the Secretary. The new Committee takes office after June next.

FURTHER NOTES AND EXPERIMENTS ON THE COMPOSITION AND MANURIAL VALUE OF SEWAGE SLUDGE.

BY J. M. H. MUNRO, D.SC., F.C.S., ETC.,
Professor of Chemistry in the College of Agriculture, Downton, Salisbury.

In January, 1885, I had the honour of reading a paper before this Society, giving the results of field experiments with filter-pressed sewage sludge upon crops of turnips; I showed that, weight for weight, partially air-dried sludge exercised rather more immediate effect than farmyard manure, and good crops were grown with all three of the sludges tried, whereas on the unmanured plots scarcely any crop could be obtained. Since, however, 5 tons of the sludges contained a considerably greater weight of phosphoric acid and nitrogen than 5 tons of the farmyard manure, I considered that I had by no means obtained the maximum effect, which I attributed to the fact that the sludges were used in tenacious clods not readily pulverised by the harrow so as to mix with the soil. I expressed my intention of experimenting with some dried and ground sludges, anticipating that from them much better duty per unit of nitrogen and of phosphoric acid would be obtained.

These trials were duly made, with all the care I could bestow on them, but circumstances beyond my control interfered greatly with the results. Thirty-five plots of rape were grown in 1885, and some experiments were made on potatoes also; nothing was wanting to success but suitable weather, and unfortunately the summer of 1885 is too well remembered as one of exceptional drought. Root crops failed almost entirely over the whole of the south of England, winter keep was consequently exceedingly scarce, and the price of sheep fell alarmingly at the autumn fairs. My experimental plots of rape and swedes were really the best specimens of those crops to be seen on the farm, but that is not saying much; the weather was far too dry to favour the action of any manures, and even Peruvian guano, superphosphate, and nitrate of soda, produced only a fraction of their usual effect.

In consequence of this, I postponed publication of the results, and laid out another series of thirty-five plots in 1886, on which a mixture of rape and turnips was grown; these also were sacrificed to a misadventure, for which science provides no remedy. The farm manager, caring nothing for sewage sludge, and a good deal for the exigencies of his daily work, cast a greedy eye upon my crops as they approached maturity, and finally folded a flock of sheep upon them without allowing me any opportunity of weighing up the produce. I cannot, therefore, pretend to offer in this paper anything very new or very conclusive; as the title indicates, I have, really in response to the invitation of your Hon. Secretary, put together such notes and observations as may furnish a record of the work I have been able to devote to the subject during the past two years. The very full and recent discussion on the disposal of sewage sludge following the reading of Mr. Dibdin's and Mr. Crimp's papers at the Institution of Civil Engineers, proves the interest and importance of the subject, but at the same time, perhaps, rather discourages any individual effort to add to the existing information.

I will first dispose of the field experiments with ordinary sewage sludges, and with a novel one, and then consider the composition of sludge, and how sewage can best be precipitated and the sludge pressed *with the view* of utilising the pressed cakes as manure; and this, I may be allowed to point out, is not quite the same thing as precipitation and pressing with the sole view of clarifying sewage and avoiding a nuisance.

The ordinary sludges tried as manures in 1885 were Coventry sludge (lime and alumina), Leyton sludge (Hanson's process, lime and alkali waste), native guano (A B C process): all air-dried and ground. Wimbledon sludge (lime) partially air-dried and in lumps. Besides these, I tried also a sludge precipitated *not* from sewage, but from the waste liquor of a hide-cleansing factory. In its dry state it contained 1·20 per cent. nitrogen, and only 0·80 per cent. phosphoric acid.

The plots receiving these sludges were compared with unmanured plots, and with plots receiving standard manures, such as nitrate of soda, mineral superphosphate, Peruvian guano, and fish guano.

The detailed analyses of these sludges (together with others) are given in Table A, and will be commented on after the manurial results have been given.

From this table we find that eight samples of sewage sludge tried as manures, prepared in six different towns, by lime or alumina precipitation, or both, contained on the average in 100 parts of dry matter 2·20 per cent. of phosphoric acid, equivalent to 4·80 per cent. of phosphate of lime, and 1·40 per cent. of nitrogen equivalent to 1·71 per cent. of ammonia. Mr. Dibdin gives as the average composition of the (dried) sludge obtained at Crossness 1·57 per cent. of phosphoric acid, =3·42 per cent. of phosphate of lime, and 2·08 per cent. of nitrogen, =2·53 per cent. of ammonia. In bone manures, some of which contain about the same percentage of nitrogen as dried sludge, 13s. per unit of nitrogen reckoned as ammonia is not considered a high valuation; and as to precipitated phosphate, it may be put at 2s. per unit. I mean that farmers should be well content to pay these prices at industrial centres for manure in the condition of dried and ground sludge, free on rail, but exclusive of carriage; they generally pay very considerably higher figures, because they buy inferior manures in small lots through local dealers on credit. For example, many so-called samples of bone superphosphate contain not more than 0·6 per cent. of nitrogen reckoned as ammonia, and even this small quantity is generally paid for at more than 13s. per unit. Again, by getting close quotations from London makers a farmer could no doubt buy 10 or 20 tons of mineral superphosphate at 1s. 9d. per unit of "soluble phosphate," exclusive of bags, carriage, and credit; but farmers generally pay 2s. 6d. to 3s. per unit, and an educated farmer, in talking to me, refused to believe that this manure could be of good quality under £4 10s. per ton, that is 3s. 6d. per unit of soluble phosphate. On the basis given above we get 31s. 9d. on my analysis, and 36s. on Mr. Dibdin's, as about the value of the manurial constituents of one ton of dried and ground sewage sludge. I contended that there is nothing to prevent this valuation being justified, when the ground sludge is applied to crops and property mixed with the soil, side by side with well-known artificials bought at market rates. I am aware that these figures give nearly 15s. per ton as the value of the wet pressed sludge containing 55 per cent. water; but I have never contended that sludge from the presses is worth 15s. per ton. Its unsuitable physical condition was fully dwelt on in my previous paper. At Salisbury, during the last few months, 1000 tons of this stuff have been sold at nearly 4s. per ton on the spot; the railway company would deliver stable manure from London for about 6s. 6d. per ton at this distance. Bearing in mind that under favourable circumstances these two manures will in the first year produce nearly similar crops, weight for weight, a much higher price than 4s. cannot be expected; at the same time, the farmer using good sludge leaves in the soil a much larger residue of phosphoric acid and nitrogen, to be partly utilised in future years, than is left by an equal weight of farmyard dung.

So long as Local Boards can get anything for the sludge, or even give it away, they will probably not trouble about any further preparation of it. But where other manures are cheap, and the sewage works not in the midst of an agricultural district, 4s. cannot be obtained; at Coventry, 2s. 6d. is all that can be had; at Wimbledon, where stable manure competes with it, 1s. per ton is obtained; at Leyton it is given away; at Tottenham it is partly given and partly *delivered to* the farmers; and at Crossness, where it would be produced in very large quantities, quite away from the country, competing with stall manure, fish waste, and other refuse requiring to be sold, and close to the spot where artificial manures can be bought cheaper than anywhere else, it would seem as if no mode of disposal or of utilisation can save sewage sludge, pressed or unpressed, from being a burden to the rates. What will eventually be done with the London sludge I leave to others to discuss. My present object is to point out that in smaller towns, where the pressed sludge is not easily disposed of, but is not produced in too great a quantity, or too far from an agricultural district, a manure can be produced by drying and grinding, which, at all events, should more than repay the cost of these two processes.

Let us see now how my estimate of 30s. per ton dry, is justified by trials against other manures, first remarking that in field experiments of this kind negative results are of no value. A manure *cannot* under the most favourable circumstances do more than yield up a certain fraction of its fertilising ingredients to a crop, but, on the other hand, many circumstances may prevent even the best manure from producing any appreciable benefit in particular cases. To ensure success, the soil must be in poor condition, otherwise the unmanured plots will yield too highly; the crop must be one which will respond to the "dominant constituent" of the manure—root crops for phosphates, gramineous crops for nitrogen, potatoes or clover for potash, etc.; the manure must be in proper condition (*i.e.*, generally in powder), and properly applied at the right time; a uniform plant must exist over the plots; the soil must be uniform in character; *and there must be sufficient rainfall to render the manure available to the plant.* Lack of the last condition was fatal to many of the plots of rape in 1885; for want of rain just after sowing the plant failed in patches, most over the unmanured plots, and next over those receiving the weakest and most insoluble manures. The six unmanured plots produced an average of 153lb. green rape; the *best* plots, those receiving farmyard-manure and enriched sludges only produced about 450lb.—three times this quantity would have been a fair crop had there been sufficient rainfall. Owing to the patchy nature of the plant, the plots receiving—

4cwt. per acre, herring and potash guano
1½ tons ,, hide cleansing factory sludge
3 tons ,, native guano
1½ tons ,, nativo guano
3 tons ,, Coventry sludge

showed either insignificant increases over the unmanured plots (the herring and potash guano showed a *decrease*), or increases so irregular that no conclusions can be drawn. Coming to the plots on which a more uniform plant was secured, the following averages were obtained:—

	Increase. lb.
Unmanured, 153lb.	0
1½ tons per acre, Wimbledon sludge, 254lb.	101
1½ tons ,, Coventry sludge, 261lb.	108
4cwt. ,, superphosphate, 278lb.	125
8cwt. per acre, superphosphate, 328lb.	175
4cwt. ,, codfish guano and potash, 295lb.	112
1½ tons ,, dried and ground Leyton sludgo (moisture 27 per cent., nitrogen 1·05 per cent., phosphoric acid 1·28 per cent.), 345lb.	192
10 tons per acre, farmyard manure, 449lb.	296

Taking the four best results, the 8cwt. superphosphates, costing us 24s., and the 4cwt. codfish guano, costing 32s., were both inferior to the 1½ ton dried and ground Leyton sludge, worth, according to my valuation, 28s. 6d.; the 10 tons farmyard manure, which if bought would cost in our district perhaps 65s., produced about as great an increase over the Leyton sludge crop as would be expected from the difference in the price at which they are valued.

The ground Leyton sludge (precipitated by Hanson's process) was of a peculiar light feathery texture, different to what I have seen in any other sludges. I do not know the reason of this, but perhaps it partly accounts for the good result obtained with it.

Experiments made in the same year (1885) on potatoes, grown in a different soil, and in a different locality, show that dried Coventry sludge and Native Guano (the only sludges tried) justify the value here assigned to them, in comparison with fish-potash Guano and Peruvian guano. In this case the potato sets were a yard apart each way, and a carefully-weighed quantity of the manure was incorporated with the soil above each set at the time of planting, experiments reported by me elsewhere (*Agricultural Gazette*, September, 1884), having shown that the yield of tubers could be more than doubled according to the mode of applying the manures, and that this mode was the best of those tried. In 1885 the results were:—

39 sets of potatoes unmanured, produced on an average	61lb. tubers.
39 sets, each manured with 4oz. dried and ground Coventry sludge, @ 13½% moisture, 1·06% nitrogen, and 1·25% phosphoric acid, produced on an average	76lb. ,,
39 sets, with 8oz. each of the same sludge	86lb. ,,
39 sets, with 8oz. each Native Guano, at 29% moisture, 1·50% nitrogen, and 1·42% phosphoric acid	74lb. ,,
39 sets, each with 1oz. fish guano, containing 8% nitrogen, 7½% phosphoric acid, and potash salts	78lb. ,,
39 sets, each with 2oz. of the fish guano	102lb. ,,
39 sets, each with 3oz. Peruvian guano, containing 8% nitrogen, and 11% phosphoric acid	114½lb. ,,

The Peruvian guano cost £10 per ton, the fish guano £8; the native guano comes, on my valuation, to 29s. 6d. per ton, the Coventry sludge to 22s. 6d. Applying these figures, we find that—

4oz. per set Coventry sludge gave an increase of 12lb. potatoes, at a cost of	1d.
8oz. per set Coventry sludge gave an increase of 22lb. potatoes, at a cost of	2¼d.
8oz. per set Native Guano gave an increase of 10lb. potatoes, at a cost of	3d.
1oz. per set Fish potash guano gave an increase of 14lb. potatoes, at a cost of	2d.
2oz. per set Fish potash guano gave an increase of 38lb. potatoes, at a cost of	4¼d.
3oz. per set Peruvian guano gave an increase of 50¾lb. potatoes, at a cost of	7¾d.

Without analysing these numbers more minutely, it is evident the comparison is by no means unfavourable to Coventry sludge at the value affixed to it.

The only other manurial results I have to bring forward are those obtained with specially prepared sludges, enriched by the use of phosphatic material in treating the sewage.

The idea of precipitating sewage by dissolved phosphates is very old, and is associated with the names of Herapath, Blythe, the Phosphate Sewage Co., Dugald Campbell, and Whitthread. The novelties in the present experiments are two, and refer to the phosphatic material employed, and the time of introducing it into the sewage. In 1884 and 1885 I was employed in demonstrating the manurial value of the phosphates contained in basic cinder, or Thomas phosphate slag, and it was while this work was on hand that the idea occurred to Mr. C. C. Hutchinson and myself of utilising this substance for sewage treatment. Thomas slag was then a waste product, and consequently by far the cheapest phosphatic material to be bought; it is still considerably cheaper than other phosphates, but as the experiments made in 1885 by Professor Wrightson and myself, and a number of experiments made in Germany by Dr. Paul Wagner and others, have demonstrated the high manurial value of this slag, when simply ground to a very fine powder, it can no longer be obtained at a waste product price.

Thomas phosphate slag now contains on an average 17 or 18 per cent. of phosphoric acid, equivalent to 37 or 38 per cent. phosphate of lime. It is distinguished from other phosphatic materials by the presence of 12—18 per cent. of protoxide of iron, together with some peroxide.

When this slag is ground and treated with sulphuric acid, there is obtained a "superphosphate" of a peculiar character; in addition to the soluble phosphate, it contains a considerable proportion of ferrous sulphate, some ferric sulphate, and a large excess of sulphate of lime. The manurial efficacy of this "dissolved slag" appears to be to some extent interfered with by the sulphate of iron, and is at present eclipsed by the superior results shown by the undissolved slag when finely ground. As a sewage precipitant, however, the sulphate of iron is an advantage. The soluble phosphate has also precipitating power, and the phosphoric acid is recovered in the sludge. The drawback to the process is the large percentage of lime contained in the slag—about 20 per cent. in excess of the phosphoric acid, and the consequent large proportion of sulphuric acid required to dissolve it. Could a phosphatic slag be produced, with this excess of lime nearly replaced by protoxide of iron and phosphoric acid, it would be very suitable for this method of sewage treatment.

In June, 1885, some experiments were made by Messrs. S. H. Johnson, C. C. Hutchinson, and myself, at the West Ham Sewage Works, with the view of obtaining a highly phosphatic sludge to be dried and ground for manure; and the manure produced was tried against the other sludges in the field trials already cited. I will summarise very briefly these experiments, which disclose some points of interest. The West Ham sewage is notorious for being very foul, very much contaminated by manufacturing refuse, and liable to vary in composition with great suddenness; hence it has always been found difficult to treat by chemical processes. A preliminary series of precipitation experiments in gallon jars was therefore made, from which we learned—

I. That dissolved cinder alone tried successively in quantities of 3, 5, 10, 16, 20, and 40grs. per gallon, produced no satisfactory precipitation. The dissolved cinder was of course precipitated by the ammonia of the sewage, as is the case with the sulphate of alumina in the A B C process, but the precipitate so produced failed to clarify the liquid, and bring about speedy settlement. All the mixtures remained alkaline after standing for half-an-hour.

II. 40grs. dissolved cinder per gallon, followed by the successive addition of 1½, 1½, and 3grs. of lime (as milk of lime), produced a more satisfactory effluent, but the effect was much better when the 6grs. of lime were added in one dose, directly after the dissolved cinder, instead of in instalments.

III. Adding the lime *before* the dissolved cinder produced a still better precipitation. This is known to be the case also when lime is used in conjunction with sulphate of alumina.

IV. 8, 6, 28, 14, and 10grs. lime were then tried, followed by 16, 24, 168, 70, and 30grs. dissolved cinder. Less than 10grs. of lime gave an unsatisfactory precipitation with this sample of sewage, but by using 10grs. with 30grs. dissolved cinder, as good a clarification was obtained as with larger quantities. These quantities gave a nearly neutral effluent, in which phosphoric acid could not be detected.

V. Raw ground basic cinder, although containing free lime, was found to have little or no precipitating power.

VI. 10grs. of lime and 10grs. sulphate of alumina gave a better precipitation than 10grs. lime alone, but 10grs. lime and 30grs. dissolved cinder gave the best of all. When the sulphate of alumina was increased to 20grs., however, it showed a superiority over the dissolved cinder.

All the above experiments were made with the same sample of sewage. The next morning a fresh sample was taken, and the trials continued. Only 5grs. of lime were found necessary to produce a satisfactory clearance, and the best result was obtained with 5grs. lime and 20grs. dissolved cinder. Another sample of sewage, taken *only half-an-hour after the preceding*, however, did not clear well with 2, 3 or 5grs. of lime, followed by dissolved cinder or sulphate of alumina, and required 10grs. lime and 20grs. dissolved cinder to produce a satisfactory clearance. In a manufacturing district like West Ham the changes in the character of the sewage are sometimes very sudden.

On the third day also of the precipitation trials the sewage required 10grs. lime and 30grs. dissolved cinder, and the effluent was not improved by substituting 10grs. of sulphate of alumina for 10 of the dissolved cinder.

Our object being to produce a sludge rich in phosphoric acid, we determined to use 10grs. lime and 30grs. dissolved cinder on the large scale, and accordingly we precipitated the contents of two tanks (about 525,000gals.) of sewage with 7cwt. lime and 19cwt. dissolved cinder. The milk of lime was added before pumping and the dissolved cinder after.

With the sludge produced in these operations a series of pressing experiments was conducted with a hand-power filter-press, in order to ascertain the minimum quantity of lime required to render the sludge pressable. The necessity for adding lime again at this stage considerably increases the quantity of lime consumed, diminishes the nominal value of the sludge, and gives rise to the very alkaline and badly-smelling press-liquor complained of by Dr. Tidy and others. (See Table B, analyses of the Wimbledon, Leyton and Salisbury press-liquors.)

The untreated sludge was, of course, found to be unpressable, and only when 1½ per cent. of lime was added could a good pressing be obtained, the time taken (in the hand-press) being half-an-hour, and the pressure rising from 60 to 100lb. per square inch.

The first large pressing was, therefore, made with this proportion, 2cwt. lime (1½ per cent.) being added as milk of lime to the 14,680lb. sludge measured in the well. It will be noticed that this is more than half the quantity used (3½cwt.) for the actual precipitation of this first tank of sludge. Good cakes were obtained, which easily came to pieces (A).

It was found by a small trial pressing that the quantity of lime required to make the sludge pressable could be diminished by employing it in conjunction with dissolved cinder. With ¾ per cent., or half the lime formerly used, perfect cakes were obtained, when 5 per cent. of dissolved cinder was added after the lime; this quantity of dissolved cinder being more than sufficient to neutralise the sludge, but not sufficient to neutralise the sludge and lime. The press-liquor obtained in this way differed much from that obtained by the use of lime alone: it was much lighter in colour and less offensive, formed no scum of carbonate of lime on standing, and was much more free from foul matter, giving slight light-coloured precipitates with a little sulphate of alumina and dissolved cinder instead of the dark green and black precipitates given by the limed press liquor.

A small pressing with ½ per cent. lime and 10 per cent. dissolved cinder also gave good cakes (C), but the press liquor, although good in quality, was acid.

Another small pressing was made with ½ per cent. lime and 10 per cent. dissolved cinder, and a further quantity of lime to neutralisation: this also yielded good cakes (D).

The large pressing of sludge from the second tank was made with ¾ per cent. lime (1cwt.) and 5 per cent. dissolved cinder (6·6cwt.) to the 233 cubic feet of sludge in the well: in one hour first-rate cakes were obtained with a good press liquor.

All the sludges, from both large and small pressings, were dried, ground, and analysed. Field experiments were made with the sludges A and B from the large pressings.

Detailed analyses of these sludges are given in Table A; here it is only necessary to give the percentages of nitrogen and phosphate of lime in the dried material:—

	$N=NH_3$		$Ca_3P_2O_8$.
Sludge A, precipitated with 10grs. lime and 30grs. dissolved cinder per gallon, and pressed with lime 1½ per cent. of sludge, contained	2·23	....	6·81
B, precipitated like A, and pressed with lime ¾ per cent. and dissolved cinder 5 per cent. of sludge, contained	1·97	....	10·57
C, precipitated like A, and pressed with ½ per cent. and dissolved cinder 10 per cent. of sludge, contained	1·26	....	14·54
D, like C, but more lime added to neutralise the sludge	1·03	....	13·10

In addition to the large percentages of phosphates these sludges differ from ordinary sludges in having the carbonate of lime partly or wholly replaced by sulphate; thus, A contained only 10 per cent. carbonate of lime, and B none at all, but 25–30 per cent. of sulphate. There is no doubt this is an advantage from a manurial point of view. Notwithstanding the considerable proportion of precipitating materials used the A and B sludges are above the average in nitrogen; this partly arises from the solubility of the sulphate of lime into which the carbonate is converted. All these sludges of course contained protoxide of iron, and were very dark in colour as they came from the press; very speedily a fine reddish-purple tint appeared on the surface, and the colour gradually penetrated through the cakes; the complete conversion of protoxide of iron into peroxide, however, was not finished when the cakes were dry and ground, but continued to go on for a week or two in the bags of ground sludge. In addition to this oxidation the ground sludge in the bags underwent a gradual oxidation of the organic matter, which kept the sludges quite warm for two or three weeks after they were stored in the manure shed at Downton.

Here I may say that, admitting the utility of ferrous salts as precipitating agents, I can by no means agree with Mr. Dibdin's theory of their action—the idea of precipitated ferrous hydrate acting as a carrier of oxygen to the organic matter of sewage appears to me fanciful in the extreme. Mr. Dibdin says "it is rapidly converted into ferric hydrate by the oxygen dissolved in the water." But sewage, as has been shown in the experiments of Angus Smith, in my own, and in Gayon and Dupetit's, is the special habitat of *denitrifying bacteria*—organisms so greedy of oxygen that, in presence of organic matter capable of oxidation, they will take oxygen from *nitrates* in solution, when they cannot get it from the air, and hand it over to the organic matter. Hence sewage never contains nitrates until these bacteria have died down, and hence it contains no dissolved oxygen either—what was there has been used up long before. It is *these* bacteria that are the active agents in burning up the organic matter by transference of atmospheric oxygen, and they are followed by an organism of a totally different stamp, the nitrifying organism, which oxidises the ammonia to nitrate, and so completes the purification. Ferrous hydrate under the surface of the liquid remains ferrous hydrate (if it does not become ferrous sulphide); exposed to the air it quickly becomes ferric hydrate, as in the sludge cake now being considered, and then *remains* ferric hydrate unless the cakes should be again submerged. At any rate I have seen no proof that it acts otherwise.

The sludge A, pressed with 1½ per cent. of lime, has always given off a strong odour of ammonia; the sludge B, with half this quantity of lime, and this neutralised by the dissolved cinder, has never smelt of ammonia.

Now, as to the manurial results obtained with A and B.

It will be remembered that the unmanured plots of rape produced on an average 153lb. rape, and that the best of the ordinary dried sludges—that from Leyton—gave 345lb., or an increase of 192lb. when applied at the rate of 1½ tons per acre. As compared with these results—

1½ tons per acre of A gave 350lb. rape, or an increase of 197lb.
1¼ „ B „ 450lb. „ „ 297lb.

the latter crop being identical with that obtained by the dressing of 10 tons per acre farmyard manure, the best of the series. If the 10 tons farmyard manure cost, as I have said, at least 60s., the B sludge must be worth 40s. per ton; valued on the scale I have already given (2s. per unit of phosphate of lime, and 13s. per unit of ammonia), we get for the B sludge (with 10 per cent. moisture, as used) 42s. per ton, and for the A sludge (with 15 per cent. moisture, as used) 38s. 6d. With the remainder of the A and B sludges, mixed together, an entire acre of swedes was grown in another field, 8cwt. per acre of the dried sludge being drilled in with the seed. The remainder of the field was dressed with 4cwt. superphosphate per acre. The strip dressed with the dried sludge was the best in the field; on this portion the crop was fairly uniform, and roots of a fair size were obtained; on the rest of the field the crop was very patchy, as was generally the case in our district. Taking into account the very exceptional dryness of the season, I think it may be said that the manurial results obtained with these sludges were very fairly successful.

On the whole, although not altogether prepared to recommend the dissolved cinder as a precipitating agent, it appears to be a very good substance with which to press the sludge—effecting an economy of lime, greatly improving the press liquor, and conferring additional manurial value on the sludge. As regards the presence of sulphate of lime in the press liquor and effluent, Warington has shown that this substance greatly accelerates the nitrification of ammoniacal solutions; hence it appears to be desirable rather than otherwise, at any rate when the effluent is to be used for irrigation—the best way of disposing of it.

As the average composition of the dry matter of ordinary sewage sludge we get (from Table A):—

Organic and volatile matter	30·95,	containing nitrogen	1·42,	equal to ammonia	1·72.
Ash	69·05	„	P_2O_5 .... 2·20,	„	$Ca_3P_2O_8$ 4·81.
	100·00				

Of this ash 21·22 consists of clay and sand, and in the four samples analysed 29·72 consists of carbonate of lime.

Mr. Dibdin's average analysis of a number of samples of pressed sludge obtained at Crossness gives, when calculated out in the same way—

Organic and volatile matter .... 39·80, containing N .. 2·08 = NH_3 .... 2·53.
Ash................. .. 60·20 „ P_2O_5 .. 1·57 = $Ca_3P_2O_8$ .. 3·43.
100·00

The sludge analysed by Mr. Dibdin, was, it is to be supposed, produced with a minimum quantity of precipitating material—the 3·7 grains lime, and 1 grain sulphate of iron per gallon recommended for the treatment of the Metropolitan sewage. Where lime is used, as it is a cheap precipitant, and when used in sufficient quantity always produces a clear though not pure effluent, there is a tendency to use it in excessive quantities: the necessity of adding lime to the sludge to make it pressable increases the waste. The sample of Salisbury sludge (Table A) thus contains as much as 65 per cent. of its dry weight of carbonate of lime, and is, of course, correspondingly poor in nitrogen and phosphates. In considering the manurial value of sludge, its variability of composition is an important factor. In my own analyses the nitrogen per cent. of dry sludge varies from ·88 in Salisbury sludge and ·96 in Wimbledon sludge with the lime process, to 2·16 in "Native Guano" (A B C process), and 2·28 in West Ham sludge (lime and alumina). The phosphate of lime is still more variable; 1·44 per cent. in the Salisbury sludge, about 5 per cent. in several others, and as much as 9·75 per cent. in one sample of Wimbledon sludge.

From Dr. Wallace's analyses of twelve different makes of sludge (not pressed sludge, and therefore not calculated out in full for comparison with the preceding), I find an average of 27·96 organic and volatile matter, containing 0·90 nitrogen, equal to 1·10 ammonia.

The percentage of nitrogen contained in the organic and volatile matter of sewage sludge appears, from Dr. Wallace's analyses, to be 3·22, from Mr. Dibdin's, 5·22, and from my own, 4·58. Five per cent. of nitrogen, therefore, is the limit to which dry sewage sludge would tend to approach, could we obtain it free from road detritus, and precipitating material. In actual practice, 2 per cent. is a maximum which is rarely obtained.

It would be a great advantage, if, as Major-General Scott proposed, the road detritus could be separated from the sewage in a separate tank before the sludge proper is allowed to subside. When the precipitant is added first of all, it appears that the precipitate in this first tank is richest in nitrogen; but if the road detritus be allowed to deposit in a first small tank, and the precipitating agents added between the first and second tank, a different result ought to be obtained. Perhaps, on an average, not less than 50 per cent. of dry sludge consists of road detritus, and if this could be removed by a preliminary settling, the manurial value of the second sludge would be nearly doubled. The road detritus sludge could be burnt in destructors, and only the second sludge sold as manure.

Next to the adoption of this measure, which I should like to see tested practically, economy of precipitating materials is the chief means by which a rich sludge can be produced. Theoretically, the quantity of precipitants ought to be adapted to every charge of sewage in the tanks; this, however, is impossible, and the plan of automatically regulating the supply of lime by the flow of sewage falls very far short of the requirements of the case. The difficulty can best be met by habitual observation of the sewage on the part of the manager, and an avoidance of the tendency to work up to the maximum quantity of lime and stick to it. When sulphate of alumina is used as well as lime, more economy is observed, and a richer sludge produced. There is no doubt that, as Mr. Dibdin says, the lime ought to be applied in solution (as it is in the press liquor), and this is to be accomplished by preliminary agitation of the milk of lime with a sufficient volume of sewage to dissolve the whole of it. When we come to pressing the sludge, the practice of shovelling in lime wholesale is also to be discouraged; if the preparation of sludge manure is undertaken seriously, the lime added at this stage ought to be neutralised by superphosphate or dissolved basic slag, as I show in another part of this paper. By doing this, lime is economised, the manure enriched (of course the soluble phosphate is recovered), the press cloths last longer, and the press liquor is much less offensive. The dried sludge also does not part with ammonia. In the late discussion at the Institution of Civil Engineers, an agricultural chemist doubted whether the nitrogen of sewage sludge has any manurial efficacy. If Mr. Lloyd had observed the strong ammoniacal odour continually given off from limed sludge, he would not be sceptical on this point. Mr. Sillar, the champion of a limeless process, went to the opposite extreme. "By the addition of lime to manure," he says, "the whole of the ammonia is discharged into the air, rendering the manure comparatively worthless for agricultural purposes." Somewhere between these two extremes lies the truth. Ammonia is certainly given off continuously, but the process is gradual, and in the mere drying of a limed sludge, very little is lost. To test this point, I dried 20grms. of limed (Wimbledon) sludge, containing 56 per cent. water, in a Liebig's tube plunged in boiling water; a current of air was aspirated through the tube, and the evolved ammonia received in standard acid and determined. The original sludge contained 0·4195 per cent. of nitrogen, and ·0095 or $\frac{1}{44}$ of the whole amount, was given off as ammonia in drying.

Amongst all the ordinary sludges which I have tried as manures, Native Guano, on the dried sample, contained most nitrogen, = 2·62 per cent. of ammonia; and the phosphate of lime was also good—viz., 4·37 per cent. The lot actually sent me for experiment, however, contained no less than 29½ per cent. water—quite 15 or 20 per cent. more than there ought to be in a sludge dried for transit to any distance. Perhaps the reasons why this company produces a very fairly rich sludge, are that at Aylesbury they have to deal with sewage precipitable with a small proportion of reagents, and that great attention is bestowed by the management there on proportioning the precipitants to the sewage to be treated. Much has been heard about the action of the clay and charcoal in carrying down ammonia, and even the alumina has had this action claimed for it. I do not know of any published experiments actually proving this, and I doubt if experience on the large scale has confirmed it. At any rate, as Mr. Dibdin has shown, the "Native Guano" produced at Crossness (where, perhaps, they found a much larger quantity of precipitants necessary than at Aylesbury), was actually poorer in ammonia than Mr. Dibdin's limed sludge. During the last few days, I have made a few experiments to test for myself any precipitating action for ammonia possessed by the A B C materials.

A solution of ammonia containing 11grs. NH_3 per gallon, was divided into lots of 500cc. each, in glass jars covered with ground glass plates. The following precipitants were then added to the various jars :—

I. 14grs. per gallon China clay made into an emulsion with water.
II. 140grs. per gallon China clay made into an emulsion with water.
III. 140grs. per gallon China clay made into an emulsion with water; 280grs. per gallon common salt being previously added to the solution to promote coagulation of the clay.
IV. 28grs. clay per gallon, followed by 28grs. alum in solution.
V. 112grs. clay per gallon, followed by 112grs. alum in solution.
VI. 28grs. alum per gallon in solution.
VII. 112grs. alum per gallon in solution.
VIII. 28grs. per gallon freshly-burnt animal charcoal (bone black).
IX. 112grs. per gallon freshly-burnt animal charcoal (bone black).
X. No addition.

After standing for two days, 250cc. of the clear liquid were pipetted off from each jar, and the ammonia still in solution distilled off into standard acid and determined. The distillate of No. X. (nothing added), required 7·8cc. standard acid for neutralisation, agreeing with the calculated quantity; and the distillate from every other jar came within 0·1cc., more or less, of this amount. Caustic soda was, of course, added to the alumed solutions before distillation, to liberate the ammonia fixed by the sulphuric acid. It appears, from these experiments, that neither alum, clay, nor charcoal, nor the first two together, carried down any appreciable quantity of ammonia, even when used in the proportion of 140grs. per gallon. The value of the clay as a weighing material was, however, very evident; the precipitate of alumina and clay settled into a much smaller space, and in much less time than the precipitate of alumina alone; and, conversely, the clay was carried down by the alumina far quicker than it settled by itself.

Grains per Gallon.	Wimbledon Press Liquor.	Leyton Press Liquor.	Salisbury Press Liquor.
Total solid matter	237·6	470·1	354·6

Oxygen taken from $KMnO_4$ in four hours	—	9·4	—

Incineration of Sludge.—This has been tried at Leyton during the year, the pressed cake being partly dried, and then burnt with the aid of coal. Mr. Dawson, to whom I am indebted for these particulars, says that although the sludge could be burnt without creating a nuisance, the plan has been abandoned on account of expense. Six tons of pressed sludge furnished one ton of ash, and if this could be sold at 10s. per ton it would have paid expenses. A sample of this ash was analysed by me, last July, with the following result :—Calcium carbonate (with a little sulphide), 20·23; quicklime, 26·33; oxide of iron, etc., 13·6; sand and insoluble matter, 28·8; phosphoric acid, 1·60, equivalent to phosphate of lime, 3·50. On account of the considerable proportion of caustic lime the sludge ash was tried as a precipitant of sewage, and for pressing the sludge,—it failed in both capacities. As a manure the phosphate of lime would make it worth from 3s. to 7s. a ton, according to its observed efficacy. Two-thirds of the calculated manurial value of dried sludge is due to nitrogen. If the expense of drying sludge be undertaken at all, it can hardly be worth while to burn off two-thirds of its manurial value for the sake of reducing the weight of the dried material by one-third or less (dried sludge generally gives over 70 per cent ash).

Press Liquor.—I have procured samples of press liquor from Mr. Crimp, of Wimbledon, Mr. Dawson, of Leyton, and Mr. Bothams, of Salisbury. They yielded, on analysis, the results given in table on previous column.

Of these press liquors, that from Wimbledon was by far the best—light in colour, quite bright, and of less evil odour than the other two. Analysis showed it to contain very much less organic matter. These liquors are saturated solutions of lime in the organic liquid, and, as observed by Mr. Crimp and others, when added to crude sewage they very readily precipitate it. Since press liquor contains nearly 100 grains lime per gallon, 1 gallon added to 20 gallons sewage supplies 5 grains per gallon of lime in the form recommended by Mr. Dibdin—viz., in solution. I agree with Mr. Crimp that this is, perhaps, the best way to dispose of the press liquor. According to Mr. Crimp it only amounts to 1 per cent. of the sewage treated daily, and there is no accumulation. At any rate, when the effluent is used for irrigation this is the proper way to dispose of it. Probably the very bad odour of press liquor is due not so much to products of putrefaction as to products of the action of the caustic lime on the nitrogenous matter of the sludge. The sample of Wimbledon liquor shown has remained perfectly bright for some weeks in the bottle. There seems to be too much lime present to allow of bacterial decompositions. That the liquor is really saturated with lime I proved by shaking it with finely powdered slaked lime for some days. The alkalinity was increased by only 2 grains per gallon. No precipitation of dissolved organic matter takes place when the liquor is neutralised by an acid. The quantity of permanganate decolourised by it is very large (the Leyton press liquor speedily decolourises half its volume of the solution generally used in water analysis), and the odour only disappears in proportion to the completion of this oxidation.

To sum up the main conclusions of this paper, sewage sludge is certainly possessed of manurial value to the extent indicated in the experiments described in this paper and my previous one.

By drying and grinding the weight of the sludge is halved, and its manurial richness doubled; on account of the improved texture the manurial *efficacy* is probably more than quadrupled. In districts where the pressed sludge cannot be distributed on farms close at hand, drying and grinding are *necessary* to the disposal of it as manure. I must leave estimates to others, but it certainly appears that with sludge worth using at all, the increased value must repay the cost of these two operations.

When the preparation of manure is undertaken seriously, the following circumstances are desirable :—

I.—Preliminary settlement of road detritus.
II.—Economy of precipitants.
III.—Neutralisation of sludge by some form of superphosphate before pressing.
IV.—Drying and grinding.
V.—Perhaps enrichment with cheap nitrogenous superphosphatic material.

DISCUSSION.

Mr. **Sillar** said this was a question to which he had devoted close attention for many years. Dr. Munro deserved the gratitude of the public for the pains he had taken to solve a problem which must be admitted to be of vast importance, especially at this crisis, when everyone was complaining of the depression of agriculture. It was a settled conviction in his mind that, following the course of nature, the waste of the animal and vegetable life of the world should go to replenish the earth, if the earth was to continue to afford nourishment for the animal and vegetable creation. He could not conceive a more wasteful and suicidal course than to take the strength and richness of the land, after its use by nature, and throw it to pollute our rivers and destroy our sea coasts. Dr. Munro had taken the rational course of testing the value of these things agriculturally, and it was to be much regretted that his experiments with the "native guano" had been so interfered with by a bad season. It was only to be expected, however, that a manure which is prepared in a perfectly dry state should suffer disadvantage when put upon barren land in such a season as last year. It had been said that in order to make sludge useful in agriculture it should be fortified by the addition of ammoniacal manures or those rich in phosphates. Some crops, such as turnips, required a larger amount of phosphates than others; but he would himself rather apply sludge to those crops which were not so dependent upon phosphoric acid. Some people insisted that native guano had its richness increased by other manures; but that was not the case. Dr. Tidy, in his exhaustive report, had distinctly said that native guano was nothing more than the produce of sewage, plus, of course, the materials used for precipitating it; but those materials being clay, charcoal, and lime, they could have no manurial effect. During his experience four official trials had been made of this "native guano." The first was at Crossness, and was made under the supervision of the Metropolitan Board of Works. The land was divided into three parts, upon one of which no manure was put, on the second part 10cwt. per acre, and on the third 15cwt. per acre. The result showed that a dressing of 10cwt. per acre more than doubled the crop, and 15cwt. did very little more. This satisfied them that 10cwt. was a sufficient dose. But, strange to say, the benefit of the manure was by no means exhausted the first year. And the reason was that the supply to the earth of its natural food would not only produce a good crop, but leave the land stronger than it found it; thus contrasting strongly with the action of those ammoniacal manures which stimulate the land, acting not as bread but as brandy, and scourging a little more out of an almost exhausted soil. The character of the sludge naturally depended upon the process by which it was taken out of the sewage. Precipitation must be the means employed; but sludge which resulted from simple subsidence was almost worthless. Our best chemists had declared that the manurial value of human excreta was almost wholly contained in the urine. Liebig had estimated the value at 8s. 7d. per ton, of which he credited the 7d. to the dung and the 8s. to the urine. If one took the mixed matter from the sewers and allowed it to settle, one got the solid portion, but none of the matter in solution. It was, however, the experience of farmers that the solid deposit was almost worthless; the part which had valuable manurial properties—the urine—having been run off with the effluent water. And this dissolved matter was not only that part of the sewage which had the highest manurial value, but it was also the principal cause of the pollution of our streams. Therefore, it was now recognised that in any treatment of sewage the dissolved impurities must be taken out as well as the suspended impurities, if the manure was to be worth having. Precipitation processes were divided into those in which lime was used and those in which lime was not used. He might be thought to exaggerate when he said that lime caused serious loss of ammonia. But it was so. By adding sufficient lime all the ammonia would be got out. At Aylesbury the use of lime had been abjured for the double reason that by driving away the ammonia it injured the manure and rendered the effluent water alkaline and dangerous to fish. Sulphate of alumina, charcoal, clay and blood as used there, attached themselves to the dissolved impurities, bringing them into the condition of suspension, and then upon the addition of the sulphate of alumina all the impurities were thrown down together—at any rate sufficient of them were precipitated to render the effluent water admissible into any running river. He did not know whether he had exactly caught Dr. Munro's meaning when he said that he had made the experiment of mixing ammonia and water, and trying the mixture by the A B C process. But he knew that Dr. Tidy had reported that he found the percentage of combined nitrogen in the manure to be remarkably constant, averaging 3·8 per cent., reckoned as ammonia, while the phosphoric acid was 5 per cent., reckoned as tricalcium phosphate. These 3 per cent. of ammonia and 5 per cent. of phosphates must have been carried down by the precipitants, for they were not to be found in either the clay, the charcoal, the blood, or the sulphate of alumina. The effluent water from this process was clear and inoffensive; but if lime were added to the sludge it became horribly offensive. Some farmers, however, hardly cared for a manure that was not offensive. Still they had to bear in mind that they had not only to produce a manure to please the farmers, but they had also to purify the water and avoid distressing the neighbourhood. With respect to the agricultural value of the manure, he (the speaker) had collected evidence which he believed would satisfy the most sceptical. They had put it to the test of chemical analysis, and to exhaustive field tests at Crossness. It had been tried against farmyard manure and Peruvian guano, etc., and, value for value, it was better than them; for at £3 10s. per ton it beat them all. Then at Berkshire Colonel Milne Holme and Sir James Jepson had put it upon the fields and published the results, and in each case the "native guano" had beaten every other manure. They had sold thousands of tons, and never at less than 70s. per ton. He thought he had shown that sewage could be treated so as to preserve the manure in an inoffensive condition, and suitable for conveyance to any distance. Everyone wished that this question should be thoroughly understood, and that the country should no longer be guilty of waste, and of the pollution of our rivers with the strength of the land.

◆◆◆

DISCUSSION ON MESSRS. CROSS AND BEVAN'S PAPER ON HERMITE'S METHOD OF ELECTROLYTIC BLEACHING.

The Chairman said he had been much interested by this paper. Success in such fields depended on a right estimation of the value of any given process, and on its proper application. Whether one used chlorine in the ordinary form of bleaching powder, or the chlorine compounds produced by electrolysis, or ozonised air, the real question was how to get the largest amount of available oxygen with the least possible expenditure of force.

Professor Armstrong considered it would have been of much advantage to the Society if the authors of the paper had given some account of the process to which it referred. As it was, he was not quite sure what was the real claim of the inventor—whether it was simply for the production of a solution which would bleach, or for the use of a certain solution in a particular way. The process seemed to him to be merely one for the preparation of a bleaching solution. The authors, however, had expressed themselves in language so difficult to follow, that he had failed to realise the meaning of some of their statements. Their results were put forward in such a form that it was practically impossible to pass any judgment on the efficiency of the process from a mere study of the paper. The paper was unnecessarily full of expressions altogether special to the authors and difficult for others to understand. For instance, in the first part of the paper it was stated that "the chlorine in bleaching powder may be regarded as an accumulator of oxygen." The term "accumulator," as used by electricians, was convenient, but was often misleading, and such a term was not desirable in chemistry. Later on, it was said that the solution contained a large amount of bleaching compounds at a very high tension: and when one tried to find the meaning of this statement, it turned out that these bleaching compounds were soluble in ether, and would evaporate with it. That was not the usual way of describing bodies of high tension. The important part of the paper was, he supposed, contained in the passages beginning, "What we may call the primary interpretation of an electrolysis, according to Faraday's law, presupposes a complete separation of the ions. When this does not occur, and where, by electrochemical substitution, the anode and cathode are brought into relationship peculiar to a peculiar balance of the products of analysis, the law requires a modified interpretation. We shall revert subsequently to this point, as affecting the particular case under consideration." He did not understand the meaning of that passage, but it appeared to be regarded as an important one, as it was referred to by the authors later on. He thought, too, that the authors should further explain their statement that "the *bleaching* efficiency of the electrolysed solution is considerably in excess of that of a solution of calcium hypochlorite of the same *oxidising* efficiency, measured—*i.e.*, in terms of the usual standard—an alkaline solution of arsenious acid." If this meant anything at all, it meant that the solution had a higher oxidising power than ordinary bleaching-powder solution. But then it was said that "the oxidising efficiency—*i.e.*, free or active oxygen—thus measured and expressed in terms of the current, is in excess of that calculated on the basis of the electrolytic law, as directly interpreted." These statements were more or less contradictory. It was important to observe that the efficiency of this new solution was measured by means of a solution of arsenious acid—the authors had not ascertained the real efficiency of the solution. They had adopted a bad standard—one which gave a measure of only part of what was present. Later on, it was said that a certain amount of available chlorine was obtained per ampère hour, but it was not stated how that available chlorine was determined by arsenious acid. He could not understand the authors' statement that the oxidising efficiency of the solution was in excess, not only of that of a bleaching-powder solution, but of the theoretical efficiency obtainable according to the electrolytic law, except upon the supposition that the authors believed in perpetual motion. Something must be wrong, and the only possible conclusion was that the authors' interpretation of the electrolytic law was incorrect. After such a statement, it appeared to him unnecessary to analyse the figures given as proving the efficiency of the process. No data had been given as to the composition of the solution. It was said to be altogether peculiar and different from a bleaching powder solution—which was very probable—but the authors seemed to have made no attempt to determine what amount either of oxygen, or of chlorine capable of producing oxidation directly, or of oxygen-chlorine compounds, were present. They had employed merely the conventional standard—arsenious acid. Taking all the circumstances into account, the paper did not seem to advance our knowledge of the subject under discussion. No data has been given from which it was possible to determine the actual efficiency of the bleaching solution, and to arrive at such a determination, numerous and definite data were necessary. It was to be regretted that the paper had not been drawn up as scientific papers usually were, and that the authors had not given a clear statement of the methods they had employed to arrive at their facts.

Mr. **Mactear** was inclined to agree with much that Prof. Armstrong had said, but would like to start from a different basis, and say a few words on the process as he had seen it in operation recently at the Antwerp Exhibition. The process was at work there on a considerable scale, and was, of course, one which deeply interested himself. He had spent some hours in watching it at work, and had been highly delighted by the results he had seen. The employment of an electrolysed solution of this class was not new; it had been known for many years, and was, he believed, the subject of many patents. But the special apparatus designed by M. Hermite for the process was extremely ingenious, though he feared it would also prove to be exceedingly expensive. There could be no doubt, however, that M. Hermite had shown at Antwerp a perfectly practicable installation for bleaching flax yarns. He was under the impression that the figures given to him showed that the results were hardly as yet satisfactory from a commercial point of view. No doubt the authors would be able later on to bring forward further results, which would enable one more fully to compare the new process with the old. At present this new process seemed to him to be very interesting and very promising, though hardly yet in its most practicable form.

Mr. **Cross**, in reply, said that as Prof. Armstrong had brought a rather heavy indictment against the exposition of the Hermite process, he would endeavour to make a few explanations. He had closely studied the process for some months, and in doing so had had the advantage of intercourse with a distinguished physicist—Prof. Pictet. They had jointly endeavoured to work out the problems which the process presented, and any statements made in the paper represented Prof. Pictet's views on the subject as well as his own. If Prof. Armstrong told him that he could not understand the language of the paper, he could only reply that there was no possible ground for discussion between them. The subject was a difficult one, and was complicated on a variety of issues. They had brought it before this society first because, there being an installation actually at work on a large scale, the matter might be considered, from an industrial and commercial point of view, as fairly elucidated. At any rate, it was sufficiently matured to permit practical men to come to the laboratory to make their own trials and calculations, and to order apparatus for their own works based on those trials and measurements. To a certain extent the scientific and commercial sides of a question were separable, and it was a frequent experience for science to come after industry rather than before it. They had laid the industrial side of the matter before this Society; at the same time they wished to indicate the lines upon which the scientific investigation would follow. That investigation would probably be long and laborious, and the results would in due time be laid before the Society to which it properly belonged. For the end they had in view the arsenious acid standard was a good one; and it had this advantage: that the reaction involved was so simple that if the acid were destroyed it could only be in one way, by oxidation to arsenic acid; it might not measure the whole of the oxygen, but it could not err the other way. The point to be determined was the comparative bleaching effects of two solutions. One might take the time standard, but that was not the most important element. The best standard was the amount of oxygen consumed in bringing a certain weight of pulp or yarn to a particular condition. Those comparisons were given in the paper in language which, he thought, could not be misunderstood; and the numbers given had been verified, in regard to the solution, on every scale from 1 litre up to 850 litres. With regard to the important question of the electrolytic law, and the apparently excessive yield of oxygen, all he could say was, that they had taken a certain measure (arsenious acid) of the oxidising efficiency of their solution, and the numbers thus obtained, in terms of oxygen or its equivalent of chlorine, were in excess of the so-called theoretical equivalent. That was the dilemma they were presented with, and they saw no escape from it. They were bound to explain, and the explanation did not appear to be strained. The maximum error of their instruments was 1 per cent. Doubtless there were errors of language in the paper. The authors had, however, used such terms as seemed to them to convey a lucid meaning; and if they appeared to others to be nonsense, they could only express regret. He would state, in conclusion, that the results given had been obtained in various ways, and that the experiments had been conducted with all the care that men could use who had an important matter in hand. No pains had been spared by the inventor, who had, moreover, shown himself anxious to have the results obtained fully and freely criticised; and the testimony they had obtained to the correctness of those results had been so unanimous that they had felt justified in laying them before the Society. In reference to Mr. Mactear's allusion to the Antwerp Exhibition, it might be mentioned that M. Hermite had been awarded a gold medal by the Technical Jury. Since then the process and apparatus had been considerably improved.

◆ ◆ ◆

DISCUSSION ON MR. MACTEAR'S PAPER ON CASTNER'S SODIUM PROCESS.

In inviting discussion on this paper, the **Chairman** observed that its main interest lay in the fact that it opened up the possibility of obtaining aluminium at a much cheaper rate than at present. As the late Mr. Weldon had shown in one of the papers he had read before the Section, the production of aluminium by direct reduction by heat and carbon was utterly impossible—the very principle of thermo-chemistry forbidding it. Therefore, any process which gave cheap sodium, and thus rendered possible the production of cheap aluminium by Deville's process would prove of immense advantage to industry.

Mr. **Mactear** said: At the last meeting, after the reading of the paper, a gentleman had asked him what was the difference between this process and the Thompson process. He was not acquainted with the latter process at the time, but he had taken the trouble to ascertain its nature since, in case the question should be again raised. He did not know whether it was proposed to use a Bessemer converter in the Thompson process for the manufacture of sodium; but the idea was that by having a bath of molten iron they would get a decomposition of their soda salt and so obtain their sodium. The difference between these two processes was therefore very marked. In the one case molten iron was used, requiring an enormously high temperature and a special lining for the apparatus; whereas the Castner process required no molten metal, the temperature was always under 1000C., and the apparatus was extremely simple. He had had a long experience of processes, chemical and physical, and he usually found that the best proof of the difference between two processes with the same object was that one was successful and the other was not.

Mr. Johnson inquired whether there were any circumstances limiting the quantity of materials to be worked. The apparatus as described seemed enormous for so small a charge.

Mr. Mactear replied that it was evident that this was the first furnace, and that it had been built upon calculations made entirely in the dark. On that account it was hardly fair to criticise either the dimensions of the apparatus or the quantity of material worked in it.

Mr. Johnson said that was a question which would affect its commercial use.

Mr. Mactear admitted that; but a child must creep before it ran; and this was the creeping. It was intended to largely increase the charges treated. Up to the present they had been feeling their way; many points had had to be elucidated, and the results had surpassed their utmost expectations. The next furnace would be modified accordingly in construction and dimensions. No doubt much could be done in the way of cheapening the process; but, all things considered, he thought the meeting would agree with him that Mr. Castner deserved high praise for the results already obtained.

The Chairman said it seemed to him that if the process would work and give promising results on this small scale, it was almost certain to work well and develop better results on a much larger scale. It opened up a prospect of really cheap aluminium, and that would revolutionise engineering.

Mr. Mactear here exhibited a piece of bronze made from aluminium produced from the sodium process. He said it was remarkable as having been forged out cold from a *first* casting, whereas such bronzes usually required repeated meltings before they were clean enough to be forged.

Mr. C. von Buch said there was a process called the Cowles' process for producing aluminium bronze in an electric furnace. The bronze thus produced seemed to him to vary much in composition. He supposed that a bronze made like the one they had just seen would be much better than that made by the Cowles' system.

Mr. Lant Carpenter had no personal experience of bronze, but had read accounts from America with regard to its production by the Cowles' system, and those accounts certainly bore out the criticism just passed upon it. Bronze thus made must necessarily be very indefinite in composition.

DISCUSSION ON MR. MACTEAR'S PAPER ON RAISING ACIDS.

The Chairman said this was another instance of the inversion of a well-known principle, the discovery of which we owed to Dr. Sprengel. That inventor had revolutionised our ideas of physics by the discovery of his vacuum pump; and the reversal of its principle enabled one to work a siphon at a much higher level than was theoretically possible. Most practical men had had experience of a leak in a siphon, and of the wonderful power of the long leg for losing its weight. In the case of a small siphon, if the long leg were full of air, one could let a little air into the short leg; but to find this principle carried out successfully on so large a scale was extremely interesting. Of course it remained to be seen how the method would compare in point of economy with the ordinary montejus which was now generally used. For his own part he had tried many pumps, but had not yet found one which would pump acids satisfactorily.

Liverpool Section.

Chairman: Prof. J. Campbell Brown.

Vice-Chairman: Dr. F. Hurter.

Committee:

J. Affleck.
E. G. Ballard.
Ernest Bibby.
H. Brunner.
J. C. Gamble.
D. Herman.
J. W. Kynaston.
E. K. Muspratt.
Jas. Simpson.
A. Norman Tate.
A. Watt.

Local Sec. and Treasurer: W. P. Thompson, 6, Lord Street, Liverpool.

A meeting will be held at University College Laboratory, Brownlow Street, on May 4, and the following paper has been promised:—

Mr. J. W. Macdonald, "On the Manufacture of Arrowroot in St. Vincent, West Indies; its Uses and Adulterants."

May 4.—Discussion on Mr. Westmoreland's paper "On the Estimation of Sulphur in Pyrites."

Notices of Papers and Communications for the Meetings to be sent to the Local Secretary.

The Chairman (Dr. Brown) showed a novel apparatus for the production of chlorine in proportion as it is required for experimental purposes, in which compressed balls of hypochlorite of calcium and gypsum were treated with hydrochloric acid, the supply of acid being regulated by the pressure of gas in the generator.

Dr. Hamburger mentioned another apparatus for making chlorine, which he had now used for several years. It consisted of a large flask filled with hot and strong hydrochloric acid, into which a solution of sodium chlorate was allowed to drop by means of a capillary syphon. If chlorine-oxygen compounds were objectionable, the gas must be passed once or twice through strong hydrochloric acid, by which means pure chlorine was obtained. The apparatus would work for 24 hours without any attention whatever. The evolution of the gas could be regulated by the use of a weak or strong solution of sodium chlorate.

Dr. John asked the last speaker whether from his apparatus the current could be shut off very readily.

Dr. Hamburger replied that it could be shut off readily enough by simply breaking the capillary tube, when the evolution of gas ceased in a short time.

Mr. Longuet Higgins then read his paper on the Manufacture of Chlorates.

ON THE MANUFACTURE OF POTASSIUM CHLORATE BY MEANS OF MAGNESIA.

C. LONGUET HIGGINS, A.R.S.M.

The process for the manufacture of chlorate of potassium which is now carried on at James Muspratt & Son's works in Widnes was worked out in 1883 by Dr. G. Eschellmann, who at that time was chemist there. It is patented in the names of E. K. Muspratt and G. Eschellmann.

The idea of substituting magnesia in the place of lime for absorbing chlorine was not new, for Weldon had made many experiments with it on the small scale with a view to recover the chlorine and magnesia for further use. Up to the present time, however, magnesium chloride has resisted profitable decomposition. Dr. Eschellmann's objects in using magnesia were the production of more chlorate of potassium from a given quantity of muriates than would be obtained when employing lime and also chloride of magnesium, which, instead of being run to waste, like calcium chloride, could be concentrated in aqueous solution till it formed a hard mass on cooling, in which condition it is bought by cotton sizers. The magnesia used is obtained in the form of the natural carbonate, magnesite, which is found in three forms hard, soft, and earthy, the specific gravity varying from 2·8—3·08. This, besides carbonate of magnesia, contains varying quantities of $CaCO_3$, AL_2O_3, Fe_2O_3, silicate of magnesia, sand, and traces of copper and manganese.

MAGNESITE.

$MgCO_3$.	$CaCO_3$.	Insol. Fe_2O_3, etc.	H_2O.
93·40	3·40	2·70	....
97·10	1·20	1·50	...
93·00	2·25	4·20	0·40

MAGNESIA.

MgO.	CaO.	CO_2.	SiO_2, etc.
89·20	4·6	4·5	1·7
91·99	4·71	1·0	2·3
90·56	4·54	3·3	1·6
92·764	4·036	2·3	0·9
92·70	4·60	0·7	2·0

Magnesite at a lower temperature than in the case of limestone gives off its carbonic acid, leaving about half its weight of magnesia.

When well burnt the resulting magnesia is very light, quite soft like chalk, and often has a beautiful radiating columnar structure, not unlike starch. Magnesia is easily overburnt, when it becomes very hard, dense, and somewhat crystalline, the specific gravity increasing from 3·07 to 3·61. In this condition it is useless for chlorine absorption.

The Mn in the magnesite is often present in the form of dendritic MnO_2, and is converted by the burning into Mn_3O_4, which gives the magnesia a cream or rose pink colour, according to the quantity present.

Magnesia is very slightly soluble in water, and does not slake; it must, therefore, be very finely ground and suspended in water for treatment with chlorine. As may be expected, it does not absorb chlorine so readily as lime, and the temperature caused by the reaction under the same circumstances does not rise so high. The temperature of a magnesia octagon when finishing is about 110° Fahr., but of course it varies with the bulk of the liquor, strength of the chlorine, and rate of absorption. With a large quantity of liquor and strong chlorine the highest temperature ever observed is 140° Fahr. Lime liquor treated in a similar way rises to a much higher temperature.

The mass of the liquor, strength of the gas, and temperature within certain limits do not seem to vary the finished product; an octagon finished in one day with strong gas shows the same proportion of chlorate to chloride as one which with weak gas takes a much longer time to finish, and finishes at a lower temperature.

It may be here mentioned that, as Dr. Lunge has pointed out, in his paper on the conversion of calcium hypochlorite into calcium chlorate, calcium chlorate will form at the ordinary temperature, provided the treatment with chlorine is carried on long enough; 70 per cent. are converted readily, the other 30 per cent. slowly. Magnesium chlorate will also form readily at ordinary temperatures. At Widnes two octagons have been used to absorb the residual gas from the other octagons of a series, and never had strong gas. If they were allowed to finish, more than a week was required, and consequently their temperature was very low, yet in the end the reaction was as complete in these as in the others. At one time the attempt was made to hasten the absorption in a magnesia octagon by heating with steam, but in this case an undue amount of $MgCl_2$ was formed.

Damp Cl has next to no action on dry magnesia or on the precipitated hydrate dried at 212°. On the freshly precipitated hydrate suspended in water, Cl acts rapidly.

If the hydrate is dried before suspension in water, Cl does not act so rapidly on it as when it is freshly precipitated.

With lime, when the liquor turns pink, it is a sure sign that, at any rate, the finishing point is nearly reached; but it is not so when magnesia is used, for pink liquor can be obtained which contains a very large quantity of undissolved magnesia, and which will, therefore, still take up a great deal of chlorine.

It would seem as if any hypochlorite formed was converted into chlorate before the chlorine attacks fresh magnesia. With lime the reactions are $2CaO + 4Cl = CaCl_2 + CaCl_2O_2$; then in the presence of more Cl, $3CaCl_2O_2 = CaCl_2O_6 + 2CaCl_2$.

The first reaction must be very transient in the case of magnesia, for a bleach liquor cannot be made at ordinary temperatures by treating magnesia suspended in water with Cl. A sample of octagon liquor taken during some very cold weather, and which, on account of exposure and the dilution of the gas passed over it, had been always very near the freezing-point, on filtering was found to be very strongly pink-coloured, and yielded only a very slight quantity of hypochlorite to arsenious acid. In this case the reaction was complete near the freezing-point.

The proportion of chlorate to chloride in well-finished magnesia octagon liquor, usually approaches very near to the theoretical 1—5—viz., 1—5·1 or less, so that, as the Cl nearly always contains a small amount of hydrochloric acid, the loss of oxygen from hypochlorite must be very small. With regard to strength, liquors of all densities up to 1·25 have been produced, the proportion remaining the same. With lime liquors the proportion varies from 5·3—5·6, and the work is not considered bad if it averages 1—5·4. The smaller amount of chloride in magnesia liquors constitutes an important advantage of this process, about 7 per cent. less chloride being obtained with magnesia than with lime.

A very awkward phenomenon, occasionally manifested in treating magnesia with chlorine, is that the contents of the octagon will assume a semi-solid or party state at a certain stage of the reaction. This is probably due to the magnesium chloride formed combining with magnesia as an oxychloride. These octagons in the end finish as well as the others, but require rather different treatment.

With regard to the pink colour of the finished liquor, it is caused by the Mn_3O_4 in the magnesia: the more pink the magnesia the higher the colour of the finished liquor. With very pure magnesia the liquors are nearly colourless. The finished octagon liquor bleaches litmus on account of its containing a trace of free Cl. When this is boiled off, it has an alkaline reaction due to a little dissolved magnesia.

Magnesium chlorate does not decompose on boiling any more than calcium chlorate, so the octagon liquor is boiled down till about 50 per cent. of the chloride will crystallise out on cooling as $MgCl_2 6H_2O$ containing about 44 per cent. $MgCl_2$. It is not safe to concentrate any further, as the temperature rises too high and the liquor, when cool, sets so hard in the vats that there is great difficulty in emptying them. The proportion of chlorate to chloride in the concentrated liquor will then be about 1—2·8. Any calcium chloride present remains in the liquor.

The crystals of $MgCl_2$ can be readily freed from the $MgCl_2O_6$ liquor. Chloride of potassium is then added to the strong chlorate liquor, and the $KClO_3$ crystallised out. Great care has to be exercised in adding the chloride of potassium to such strong liquor, or the greater part of it will be found undissolved. As nearly as possible the theoretical quantity of potassium chloride must be added, for any $MgCl_2O_6$ left is lost, and any excess of potassium chloride combines with magnesium chloride and crystallises as the double chloride carnallite ($MgCl_2,KCl6H_2O$) along with the $KClO^3$, and is afterwards difficult to wash out. This also renders you unable to estimate the excess added by testing the mother-liquor.

On account of having such an enormous quantity of chloride in so small a volume of liquid it crystallises at first very rapidly indeed in the form of very small thin laminæ; afterwards, as the liquor cools, the crystals build themselves up into fragile needles composed of small crystals superimposed on one another, something like the carnallite needles, and quite different from the long acicular crystals obtained by the lime process. They are beautifully clean, as the chlorate boil is made in a few hours, thus having only a short time in which to get contaminated with iron from the pan. As $KClO_3$ is less soluble in $MgCl_2$ than in $CaCl_2$, the magnesium mother-liquors contain very much less chlorate per litre than lime mother-liquor, besides being very much less in quantity; consequently, the yield of chlorate is greater, 90 per cent. of the total $KClO_3$ being obtained. The lowest magnesium mother-liquor obtained contains 10grms. of chlorate per litre, the average being about 19, whereas calcium mother-liquors will not average under 30grms. per litre. Operations in the finishing-house are carried on very much as with the lime process. The liquors stand very well and seldom require renewal. The mother-liquor now contains $MgCl_2$,$CaCl_2$,$KClO_3$ and some gypsum derived from the sulphate in the muriates; a little $MgHo_2$ is also present, rendering the liquor alkaline. It is run into a still, together with a solution of the $MgCl_2$ crystals obtained from the concentrated octagon liquor, and the chlorate is destroyed by HCl, of which an excess is necessary or all the chlorate will not be decomposed. The Cl given off is sent back to the octagons.

When the still gets to a temperature of about 140° Fahr. the evolution of the gas is attended by phosphorescence, due to the decomposition of O_2Cl. Unless due care is exercised an explosion may occur, attended by a flash of light with deleterious effect on the top of the still.

Almost the last trace of Cl is steamed out, so that the liquor running off does not smell of Cl, but rather of hydrochloric acid.

The still liquor is now neutralised with magnesia, when it gives off a very strong, sweet smell, much stronger than that given off on neutralising Weldon still liquor. Metallic iron must be kept out of the neutralising well, as the hydrogen from it reduces the ferric chloride in the liquor to ferrous chloride, which is very incompletely precipitated by the magnesia as green ferrous hydrate leaving liquors which turn reddish, and go on depositing iron for some time after.

A measured quantity of a strong solution of Stassfurt kieserite ($MgSO_4 H_2O$) is then run in according to the calcium present, and the contents of the well are pumped into a settler where the iron and a great part of the gypsum settle out leaving the liquor of a beautiful green colour and very clear. Some of the gypsum is thrown down slowly in a dense crystalline form, coating the settlers and giving great inconvenience if pipes are used to convey the liquor to its destination.

The chloride of magnesium is now concentrated; formerly wrought-iron pans were used for this purpose, but were found to be so strongly acted on that they had to be abandoned, and cast-iron pots are substituted in their place.

A great deal of time and trouble has been expended in trying to stop the action of this liquor on iron, even in the case of cast-iron, but without success, as it does not seem possible to stop the evolution of a small quantity of hydrochloric acid, and consequent action on the iron at the temperature to which the liquor is raised—viz., considerably over 300° F. Magnesium chloride also acts on iron, especially wrought iron, according to the equation, $MgCl_2 + Fe + 2OH_2 = MgH_2O_2 + FeCl_2 + H_2$.

This reaction takes place even at ordinary temperatures, and is the one which renders $MgCl_2$ so destructive to boiler plates.

A higher temperature and voltaic action are favourable to the reaction. If a bright wrought-iron vessel is filled with a strong solution of $MgCl_2$, rendered slightly alkaline with magnesia and left for some time, a green precipitate of ferrous hydrate, which afterwards oxidises and turns red, shows that action has taken place. Zinc and lead are acted on in a similar manner, only more strongly. A zinc and platinum couple placed in a solution of $MgCl_2$ and warmed, gives off hydrogen abundantly.

The quantity of iron taken off when cast pots are used is very slight, but is sufficient to give the magnesium chloride a very high colour.

Clear at first, the liquor on boiling soon becomes muddy and whitish, owing to precipitated gypsum, which is soluble to a considerable extent in a weak solution of magnesium chloride. Any iron dissolved is not oxidised during the boiling, or precipitated by the magnesia present in the liquor, which retains its alkalinity throughout, or by excess of magnesia added at the end of the operation, but remains in solution as ferrous chloride which, when the magnesium chloride is cool, is converted into hydrated oxide, which oxidises and imparts to it a series of colours well known to chemical manufacturers. A violet or pink colour has often been obtained which is destroyed on the addition of water; what this is due to has not been ascertained, but may be to a double chloride of ferrous iron and potassium or magnesium.

To remove iron dissolved by the liquor the quantity is kept as small as possible by the employment of cast iron for the vessel, and it is oxidised to the ferric state when magnesia will precipitate it completely.

For this purpose the liquor is boiled up to near the finishing point and the iron oxidised, when the colour of the magnesium chloride changes from muddy white to bright yellow; the steam at this stage smells slightly acid.

Magnesia is now added and the fire dropped. The liquor settles rapidly, is very clear, and of a greenish colour. When cold enough it is packed into barrels, where it soon sets very hard.

The sediment at the bottom of the pot consists of oxide of iron, gypsum, magnesia, and about 30 per cent. of magnesium chloride. The magnesium chloride is very white, free from iron and chloride of calcium and contains 47 per cent. of $MgCl_2$.

DISCUSSION.

Dr. HAMBURGER asked what was the strength of the octagon liquor that was obtained by the magnesia process—*i.e.*, how many grammes of magnesium chlorate per litre?

Mr. HIGGINS said it varied from 1·20 sp. gr., but sometimes ran as high as 50° Tw.

Dr. HAMBURGER said with regard to magnesium hypochlorite, he had found on passing chlorine into milk of magnesia the same thing which Mr. Higgins had mentioned—namely, that a pure magnesium hypochlorite could not be obtained by the action of chlorine on magnesia. A large portion of the magnesium hypochlorite was converted at common temperatures into magnesium chlorate and chloride. The only way of obtaining a magnesium hypochlorite solution, tolerably free from magnesium chlorate, was by the decomposition of the analogous lime compound He was sorry to differ from Mr. Higgins in another case. The lecturer had mentioned that the proportion of chlorine as magnesium chlorate to chlorine as magnesium chloride was nearly the theoretical—viz., 1 to 5. That was not his experience. In fact, his best experiments yielded liquors in which the proportion was 1 to 6, and in many cases the proportion was far more unfavourable, showing that the magnesium chlorate had decomposed into chloride and free oxygen. He had previously mentioned that the magnesium hypochlorite was readily converted into chlorate and chloride. On the other hand, he had often experienced a difficulty in converting the last traces of hypochlorite in spite of using a great excess of chlorine. His experiments were made on the small scale, and he should like to ask the lecturer, whether, in working on the large scale, he had noticed the same difficulty.

Mr. CAREY said he would make no remark, except that the process was a very interesting one to the Society, and to ask with regard to the roasted magnesite, that Mr. Higgins would be good enough to forward some specimens to the Geological Society of Liverpool, as that Society, no doubt, would be much interested in them, seeing that these specimens form a new example of a natural process, of which they had all seen the results in the columnar basalt at Fingall's Cave and other similar places, whereby material ordinarily amorphous had been induced to assume a columnar structure. The magnesite before them seemed to be an example of the same kind of action, it goes into the kiln entirely amorphous, and comes out with the columnar structure very distinctly marked; and as in the case of columnar basalt, the columns are in the main at right angles to the cooling surfaces. They were all very much obliged to Mr. Higgins for having explained this new and excellent chlorate process in so clear a manner.

Dr. HURTER said there were a great many points of interest which Mr. Higgins had mentioned. In the first place, he mentioned that hypochlorite of magnesia very readily transformed itself into magnesium chlorate. That might be of some little interest to bleachers who intended to use Hermite's process for preparing bleaching liquor. This process consisted in electrolysing a solution of magnesium chloride, whereby magnesium hypochlorite was produced, which, however, very readily turned into chlorate, even during the electrolysis. He did not know whether the bleachers would be desirous of having the chlorine in the form of chlorate. Another point was the over-burning of magnesia. It was very peculiar how greatly the sp. gr. of magnesia altered on over-burning; and how difficult it was to dissolve. At first when Messrs. Muspratt began the new process, Messrs. Gaskell, Deacon and Co. burnt the magnesia for them. Dr. Eschellmann then complained about one batch that it was not burnt at all, and was simply magnesite. On investigation this turned out to be erroneous, and the magnesia contained no carbonate at all. It was intensely hard and heavy, and absolutely inert to chlorine gas. There was another point. They were told that the advantages of the process were, in the first instance, that the by-product magnesium chloride was saleable in limited quantities: and secondly, that potassium chlorate was much less soluble in magnesium chloride than in calcium chloride solutions. He should like to know to what extent this solubility differed. He thought they owed some thanks to Messrs. Muspratt for permitting Mr. Higgins to bring such an elaborate report of the new process before the section.

Mr. W. P. THOMPSON asked where the magnesite was obtained, and whether it was a sedimentary deposit, or an igneous one. He had met with it in small quantity in Serpentine, so supposed the latter.

Mr. E. K. MUSPRATT said he had not lately given so much personal attention to the process as Dr. Eschellmann and Mr. Higgins, although he had followed it, and in the initiative he took some steps with Dr Eschellman to bring about a perfect process. With regard to what Dr. Hamburger said as to the proportion obtained when absorbing chlorine by magnesia and lime, it was certainly their experience the proportion was very much more favourable with magnesia than with lime. They never got an octagon liquor exceeding the proportion of 1 to 5·2. Now, Dr. Hamburger acknowledged that the average of their octagon liquor with lime was 1 to 5·4 or 5·6, and he thought if Dr. Hamburger had made chlorate of potash some 20 years ago, when the workmen were not so skilled or careful as at the present day, he would have found sometimes with lime that the proportion of these liquors ran up from 1 to 6 and 7 and even 8. That was frequently caused owing to the carelessness of the workmen. Now, as Mr. Higgins had already told them, even with the most concentrated liquors they got a proportion of 1·0 to 5·1 and 5·2. He did not know why Dr. Hamburger's experiments on the small scale should have given him a different result. They knew perfectly well that the results were sometimes very different when carried out on a large scale. As regards the measure of the solubility, all he could say was that with the mother liquors in the lime process they very seldom (certainly in warm weather), had less than about 30 or 35grms. of chlorate of potassium per litre. With the magnesia process they had as low as 10grms. per litre, and even in warm weather it ran to 19 or 20grms. only, which showed that the chlorate of potassium is very much less soluble in the magnesium liquor than in the calcium liquor. As regards the treatment of the residue of the chloride of magnesium of course that had been one of the difficulties they had to contend with to get this chloride of magnesium in a soluble form. It was very curious that Dr. Eschellmann, who went to Strassfurt to examine the treatment of the $MgCl_2$ there, on his return advised them to put up wrought-iron pans, and they put up exactly the same pans in their works that they found by experience to be useful and desirable in Strassfurt, but much to their astonishment there was something in the liquors that they dealt with that acted upon the iron to a far greater extent than the Strassfurt liquors, and they were obliged to take refuge in the cast-iron instead of wrought-iron for the purpose of concentrating the liquor. He thought that what Mr. Higgins had read threw some light upon an observation that was made on the action of water in boilers. It was well known that when water contained chloride of magnesium it acted very rapidly on steam boilers. Apparently from their experience it had a direct action, and they got hydrate of magnesia and hydrochloric acid. When it was proposed in the year 1871 by Mr. Weldon to use magnesia in place of lime for the chlorate of potash process, Mr. Weldon's idea was to recover the chlorine or the hydrochloric acid from the chloride of magnesium, and to use the magnesia over and over again. That, he very soon found was impracticable. He thought Messrs. Gamble's had also some experience, and they knew how very difficult it was to obtain all the chlorine or hydrochloric acid from the chloride of magnesium calcination. Therefore, to really carry out this process, and make it a commercial one, it was necessary to make this chloride of magnesium in a saleable form, and in that they had succeeded. They would see from the sample that the chlorate of magnesium that was now produced was quite white and pure, purer than the German, and gave satisfaction in every way to consumers of it.

The Chairman said that the heat of neutralisation of $HClO_3$ by magnesium was probably about 15,000, whereas that by calcium was about 27,000 or 28,000. This might partly account for the increased yield of potassium chlorate, because magnesium chlorate would be more readily converted into potassium chlorate than calcium chlorate would. He also suggested that the more rapid formation of $MgClO_3$ as compared with $CaClO_3$ might be accounted for in the same way. It would be interesting to know whether at a higher temperature the $CaClO_3$ is formed as readily as $MgClO_3$, and whether calcium or magnesium would combine with the chlorine first if it were presented to both simultaneously.

Mr. Higgins, in reply to Dr. Hurter, said with regard to the difference of solubility of potassium chlorate in magnesium chloride and calcium chloride, he had made no quantitative experiments. What he judged from were results obtained in practice. In reply to Mr. Thompson, the magnesite was found in the island of Eubœa (Greece), associated with Serpentine. With regard to Dr. Hamburger's proportion of 1·00 to 5·6,* they had got nothing like that, even in the case where an octagon was heated with steam, when he did not think it was over 1·00 to 5·5. As to the last traces of hypochlorite, the hypochlorite was converted into chlorate as fast as formed, and there was no difficulty in making the conversion into chlorate complete.

REFRIGERATION AND ICE MAKING.

BY GEORGE E. DAVIS.

Our Journal already contains two valuable papers upon this subject, one read by Mr. J. J. Coleman, before the members of the Glasgow and West of Scotland Section, in May, 1884, and the other by Mr. T. B. Lightfoot, before the London Section, in March, 1886. Both these papers have largely extended the knowledge relating to ice machines, and I have carefully gone over the papers in question to avoid repetition, and, if possible, to put my remarks into a different groove, and as I have now had two years' experience of the compression system for refrigerating purposes, and also for the actual manufacture of ice, my remarks may be of use to those manufacturers who contemplate carrying on chemical processes by means of refrigeration, or commencing the manufacture of ice for sale.

Refrigerating machines have, roughly speaking, been constructed on two distinct principles; and here I deviate from the usual classification—the one, in which the expanded and cold gas is absorbed in water and is re-introduced in solution into the system; the other, in which the expanded gas, after it has done its work, is re-introduced into the system by means of a compression pump. The former we will call the absorption system, while the latter we will style the compression system.

I am not taking into account any apparatus for the production of cold by means of the melting of a solid; as, although such a one has been constructed to work with nitrate of ammonia as the active agent, yet such an apparatus could never expect to compete successfully with either the absorption or the compression system—at least so far as cost is concerned.

Carré's original machine, introduced in 1860, may be considered the type of all absorbing machines; it may be found described in most treatises on elementary chemistry published since that date. Ordinary liquid ammonia was placed in one vessel, which was connected with another destined to become the refrigerator. In use, heat was applied to the vessel containing liquid ammonia (aqua ammonia) while the refrigerator was immersed in cold water. When sufficient ammonia had passed over, mixed of course with a certain quantity of the vapour of water, the source of heat was removed and both vessels plunged simultaneously into receptacles holding cold water. Re-absorption of anhydrous ammonia by the contents of the previously heated vessel then took place, and the extremely rapid evaporation of ammonia from the second vessel lowered the temperature of the surrounding water to such an extent that it was slowly converted into ice.

The original machine was hardly one capable of finding extensive use, as the operation was not continuous; but Carré himself improved upon it, and various other improvements and modifications have been later introduced by other inventors and manufacturers. At present there are two forms of this system working in England—the "Carré Reece," made by Pontifex and Wood; and the "Kropff" system, which is of Continental manufacture. I saw both systems at work about two years ago, and was favourably impressed with the simplicity of their combinations, though it seemed to me at the time that the absorption system was not the best; why, I will describe later on.

In order to make the action of this apparatus and this system plain to you, I have prepared the diagram on opposite page (Fig. 1), which will show the principal parts of an absorption machine.

The generator A contains a strong solution of ammonia, where it is heated by means of a steam coil through which steam is constantly passed; the heat thus applied causes the ammonia to be driven out of its aqueous solution (and with the ammonia there is simultaneously a certain amount of ordinary steam developed); this mixture rises up through the analyser

B. This analyser separates (more or less perfectly) the aqueous vapour, which condenses and falls back into the generator A. From the analyser the ammonia passes into the rectifier C, where the vapour gives up its property of being superheated, and reaching the condenser D, if the plant is properly constructed, it gives up its latent heat of condensation and becomes converted into liquid anhydrous ammonia.

The two quantities of heat mentioned are taken away by cooling water. The liquefied ammonia flows from the condenser through a regulating valve E into the refrigerator F, which it should fill to a certain height, evaporating constantly and abstracting the necessary heat from the brine or water passing through a system of coils placed within the refrigerator. From the refrigerator the ammonia vapours flow through a throttling valve G into the absorber H, where they are absorbed by weak ammoniacal liquor, which is forced by the excess pressure in the generator through the body of the economiser I into the absorber. When this spent liquor has been converted into strong liquor, it is pumped by means of the liquor pump K back through the economiser coil into the analyser and generator, where the entire process just described is again repeated.

This short sketch shows clearly the action of machines made on the absorption system, and it shows also that there is much room for the introduction of modifications without altering the principle of the apparatus. In these machines ammonia is always used on account of its great solubility in water, and also because it is easy to cause its evolution by the application of heat.

We may now turn our attention to the compression system, which is at once much more simple in its arrangements than the one we have already described. Yet it is one which demands much more careful workmanship in the construction of the machinery than is the case with that working on the absorption system. I have prepared the diagram Fig. 2 to show you the principal parts of a refrigerator working on the compression system. To start with, the apparatus is charged with nearly anhydrous ammonia. The pump A receives the expanded vapour from the refrigerator coils C, and compresses it into the coils of the condenser B, in which the vapours are liquefied, from whence it escapes into the refrigerator by means of the regulating cock D, evaporating again in the refrigerator. This cycle of operations is continually going on, the vapour is being compressed and liquefied in the condenser, and re-evaporated in the refrigerator, where it is cooling the liquid which surrounds the coils.

On the compression system there are several and varying forms of machine, each one specially suited to the liquid or vapour to be employed therein. In Raoul Pictet's machine the liquid employed is anhydrous sulphur dioxide; then we have the various ether machines, and lastly anhydrous ammonia machines. I do not intend to single out these various machines, though later on I shall have to say something about the Linde ammonia machine, with which I have gained most of my experience. It stands to reason that the substance of the machine must be constructed of materials capable of resisting the medium employed. It would not do to use ammonia in Pictet's compressor any more than it would to use Pictet's liquid in a Linde machine, though ether or air may be used in either, if the condensing and refrigerating space be alike suitable.

The action of the compression machine is very simple, yet it is often misunderstood, and much irrelevant matter has been written respecting it. So lately as in September last an article appeared in *Industries* on the manufacture of ice, in which the following words occur:—

"When a body changes its condition from the liquid to the gaseous form, heat is absorbed to increase the energy of the molecules, although there need not necessarily be an increase in temperature. The heat thus absorbed without change of sensible temperature is called the latent heat of vaporisation. The quantity of this heat varies according to the liquid employed and the pressure at which vaporisation takes place. Economically the best liquid to employ will be that which has the highest latent heat, because the

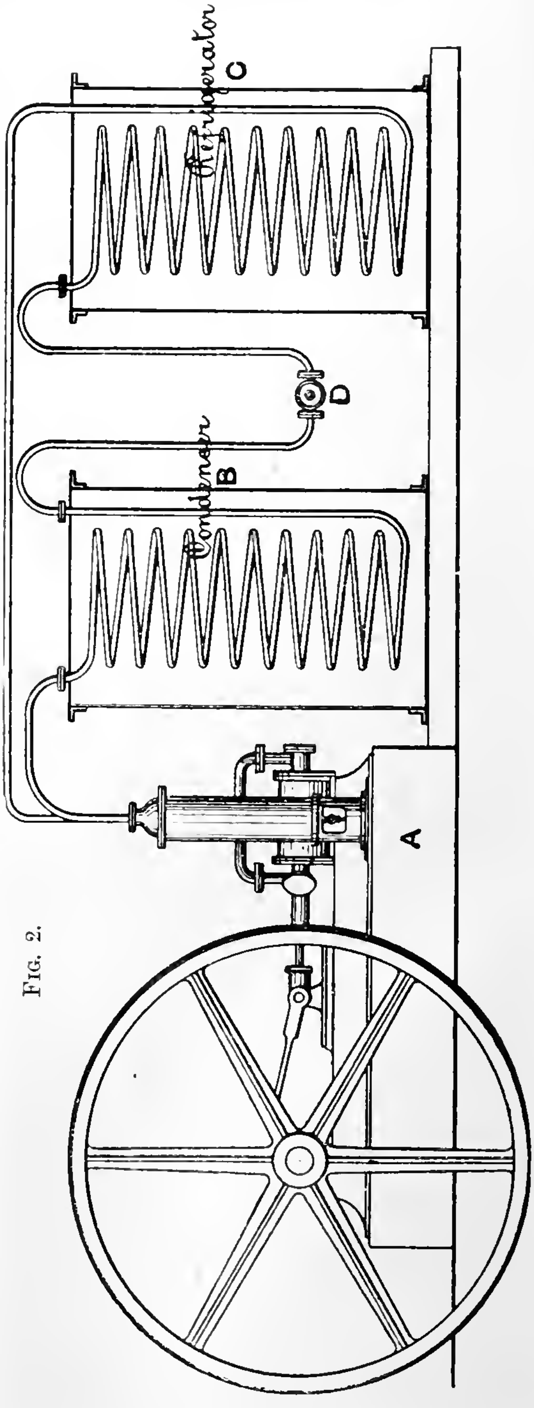

Fig. 2.

smallest bulk will suffice to absorb a given amount of heat, and consequently the least power will be used." This is wrong, theoretically; from a physical point of view, it is of no consequence whatever what compressible vapours are employed; they may be water, sulphurous acid, carbonic acid, hydrogen, oxygen, or simply a mixture of any of them, such as air. The effect of employing various media is shown however in the size of the machinery, the compressor, the condenser coils, or those of the refrigerator. For a given weight of ice to be produced a carbonic acid machine would be a very small affair compared with an air or ether machine: that is to say, if carbonic acid were a suitable medium, which I do not think it is, as it assumes the critical condition more easily under high pressures than most other vapours—proportionately. No, the action of the machines working on the compression system can be explained very easily. The expenditure of a certain amount of mechanical power W results in a certain quantity of heat R being extracted from the refrigerator, and a certain quantity of heat C is transferred to the condenser. The relation between R and C will be described later on.

A consideration of the action of the "Carnot" engine when it is reversed will easily prove that if such an engine work between the lower absolute temperature T*l*, and the higher absolute temperature T*h*, and if it receives at the lower temperature a quantity of heat H, which it gives away at the higher temperature, then a certain amount of mechanical work W is absorbed. And further, if the compression and expansion of the medium be carried out adiabatically, while the reception of the heat H at the lower temperature T*l* and its delivery at the higher temperature T*h* respectively take place isothermally, no other engine working between the same temperatures T*l* and T*h*, and carrying the heat H from the former to the latter level of temperature, is able to perform this process with a smaller expenditure of mechanical work W. That is to say, in a theoretically perfect refrigerating machine the working substances must carry out exactly the reversed process of Carnot's heat engine, provided the extraction of heat takes place at the lower constant temperature T*l*. It is further evident that for such a machine, according to the law of the conservation of energy, the relation exists:—

$$C = R + AW,$$

A being the mechanical equivalent of heat, W the mechanical work expended, R the number of heat units extracted from the refrigerator, and C the number of heat units put into the condenser. As, moreover, in consequence of the reversible cycle of operations performed by the working substance, this latter is exactly in the same state after having completed the four operations (adiabatic compression, isothermal compression, adiabatic expansion, isothermal expansion) as it was at the commencement, the second law of thermo-dynamics must be fulfilled, and consequently the relation holds good:—

$$\frac{R}{C} = \frac{Tl}{Th} \text{ or } C = R.\frac{Th}{Tl}$$

Setting the two preceding values for C equal to one another it follows:—

$$R + AW = R.\frac{Th}{Tl} \text{ or}$$

$$AW = \frac{Th - Tl}{Tl}.R,$$

or the efficiency of the perfect refrigerating machine working between the absolute temperature T*l* and T*h*—

$$\frac{R}{AW} = \frac{Tl}{Th - Tl}.$$

As the only condition in the establishment of this efficiency consisted in the operations taking place according to Carnot's reversed cycle, it follows that the above value for $\frac{R}{AW}$ applies to all machines so working, irrespective of the nature of the medium employed, whether that medium be air, ether, sulphurous acid, carbonic acid, or ammonia, or any mixture of these.

The *actual* efficiency $\frac{R'}{AW'}$, of a refrigerating machine, which is always less than the theoretical efficiency $\frac{Tl}{Th - Tl}$ will approach the maximum value $\frac{R}{AW}$ the more the smaller the difference between the higher and lower temperatures can be kept, and the importance of this rule should be well observed in the design of such machines. In practice it means that the surfaces of condensers and refrigerators must be as extended as possible, that the liquid in contact with these surfaces must be kept in rapid circulation to promote the transmission of heat, and that all refrigerating work should be performed without the production of ice or any other refrigerating medium. Further, the heat of compression must not be allowed to raise the temperature of the medium appreciably above the condensing temperature (or the temperature of the water in cold air machines), and the size of the compression pump must be kept as small as possible to reduce friction of piston and piston rod—that is to say, that liquids of great latent heat are preferable to those of lower degree on this account only.

This is clearly set forth in our Journal for 1885, p. 736, where in describing his patent, William Raydt, of Hanover, advocates the use of carbonic acid as the refrigerating medium, and states that a much smaller compression pump can be used than with other media, it being less than one-sixth the size of that necessary for ammonia; but, on the other hand, the machine must be worked under a pressure of from 30 to 75 atmospheres, and therefore a very differently constructed pump must be employed than for ammonia, where the pressures are 2 to 10 atmospheres. As I have already stated, the selection of an ice machine for refrigeration purposes forced itself upon me some three years ago, and as I finally selected one made on the compression system, in fact the Linde ammonia machine, I cannot do better than give you my reasons for this selection.

It has been mentioned that all practical refrigerating machines may be conveniently divided into two classes, and having been favourable to compression I must perforce justify my rejection of the absorption system.

The absorption system has its advantages as well as its disadvantages. Amongst the former the fact that there is no large engine to run might weigh with some; the direct heat of the steam is sent into the generator coils, so that there is but little loss in previously converting the heat into mechanical work. Of course the liquor pump still remains to be driven, but the energy absorbed by this operation is very small indeed. This seeming advantage at first appeared to be a notable one, as each unit of steam, if used direct, would be as efficient as 5 units working a compressor, but on more closely going into the matter this turned out a clear disadvantage. I managed to discover that a ton of coal produced about ten tons of ice in each of the machines I saw, the Kropff and the Carrè-Reece, and the argument was, that so much of the heat of the steam was available over and above that used in the compression system.

Now, if 12 tons of ice could be produced by this latter system, which I knew to be the case, then the quantity of cooling water used in the absorption system must be very great. In fact, in refrigerating by this system the cooling water has to absorb heat from two liquefactions of the ammonia, the first in the condenser, and the second in the absorber, where the return expanded gas is collected in the cooled weak liquor.

You will observe in Fig. 1 that the cooling water enters the lower end of the condensing tank, and flowing out above the rectifier coils enters the absorber and does some useful work there.

Attached to the rectifier is a special pipe not shown in the diagram to conduct any condensed liquor back to the analyser.

In the economiser some heat is lost by radiation. In an absorption machine working to its utmost efficiency the strong liquor will probably be heated from 40° C. to 90° C., an increment of 50° C., while the spent liquor will be cooled from 130° C. to about 60° C. I must say the existence of such a high temperature with an article like liquid ammonia in boiler-shaped vessels did not increase my love for the system, and again radiation takes place from generator and analyser which cannot be put down at less than 5 per cent. on account of their extensive surfaces.

SUBSTANCE.	Vapour Density.	Weight in grms. of 1 litre.	Latent Heat.	VAPOUR TENSIONS.			Boiling Point.	SPECIFIC HEATS.			Solubility in Water.	Heat evolved during solution in Water.

In the question of cost, absorption machines cannot compare favourably with compression machines, on account of the complication of the apparatus and the extra strength which has to be put into tubes of large diameter to resist these extremely high pressures satisfactorily. Again, the cost of filling one of these machines with ammonia is no small item; and last, though certainly not least, is the wear and tear of *hot* ammoniacal gases upon wrought iron. I have had considerable experience in the manufacture of liquid ammonia, and I am quite certain that this is an item which must be considered. I therefore came to the conclusion that the coal used per ton of ice produced was quite as great as that needed by the compression system; that owing to the large diameter of the vessels the apparatus could not be considered so safe; that the first cost would be greater; that more cooling water would be used, and that although no expensive engine tenter was required, yet a well-paid and careful superintendent was just as necessary as with a machine working on the compression system.

I thus became wedded to the compression system; and here another difficulty arose. There were cold-air machines, dry-air machines, ether machines, sulphurous-acid machines, ammonia machines, and others, the makers of which each and all asserting in the boldest manner possible that their special machine would make ice better and quicker than any other machine extant, and with less fuel and less cooling water than any other competing apparatus.

I have often had it in mind that a large and important Society, like our own, might well consider the advisability of appointing commissions to examine subjects of this kind. It is done on the Continent and in America, and upon my bookshelves I have several examples of the usefulness of this kind of work. As an instance, the examination into the efficiency of ice machines was conducted by a committee of eight engineers, selected by the Society of Bavarian Engineers, and a trial of the ammonia compression system (Linde's) was made at the ice factory at Munich. The details of this trial may be found in a paper read by Mr. T. B. Lightfoot before the Institution of Mechanical Engineers.

I have already stated that, physically, it matters not much what compressible vapours are employed, and have shown also, by formulæ, how this is so; but in practice there are various media employed in the different machines, and we ought to have some idea whether one is any better than another. In my selection, however, I was limited to a special object—namely, that of cooling 25,000 cubic feet of gas per hour from 20° C. to 0° C., and about 200 gallons per hour of a heavy oil from 30° C. to 4° C. The idea was not to make solid ice, though I believe the problem would remain the same if it had been so intended.

The formula already given shows $C = R + AW$ that the heat units C put into the condenser equal that number extracted from the refrigerator + the heat produced by the mechanical work of the compressor. This heat has to be absorbed and carried away by the cooling water; therefore it is necessary to have W as small as possible. It is here where the properties of vapour density, vapour tension, and latent heat come in, and these properties decide the size and capacity of compressor and engine in order to do a certain amount of work.

The above table will show the principal properties of the substances generally used in refrigerating machines.

A careful consideration of the foregoing table shows very clearly that physically ammonia is the best agent to use in any compression system, and, next to that, sulphurous anhydride, but it often happens in these questions that the commercial and mechanical side overbalances the physical side. With me, it was a question of refrigerating with chemicals or without them; the cost of chemicals was an unknown factor, and upon which I could get no decided information. Air was cheap enough, so I determined to investigate more closely the cold-air machines. It seemed that it would be very easy in my case to cool the gas, or a portion of it, to a very low temperature, and to mix this cooled gas with that at the normal temperature, to the temperature desired. The gas would thus be used in the machine in the place of air. Mature consideration, however, showed that the gas would enter the compressor at about 16° C. and often supersaturated with moisture, and in my case the apparatus to prevent this would have been complicated and costly. In one cold-air machine working (drawing in ordinary non-saturated air) the man in charge told me he had to open the snow chamber every twelve hours and take out several barrow-loads of "frost," so that this point of itself would have decided me had I not remembered also that the gas with which I had to deal with was mainly hydrogen, the lightest substance known.

Cold-air machines require large compressing cylinders, and as the pistons have to be perfectly air-tight, the power W in our formula must certainly be greater than when a vapour of high latent is used, especially as they have to work with a very low Tl and high Th; usually there is $Tl = -30°$ C. and $Th = +70°$ C. The cylinders would have had to be much larger if coal gas had been employed instead, to say nothing of certain complications which might have taken place by the introduction of tarry matters, and by the condensation of liquid matters from the gas. From all that I gathered it seemed to me absolutely certain that cold-air machines would require nearly four times the fuel that the best compression system would work with, and that air cooling would take more cooling water also.

After this I had the advantage of seeing the ether and Pictet's sulphurous anhydride machines almost simultaneously, and I noticed that the capacity of the ether compression-pump was about four times that of Pictet's; this, of course, meant more power to drive it, increasing the coal consumption again.

Ether is a liquid of low volatility as compared with the other media used in refrigerating machines, and of low vapour tension, so that an air-pump of large dimensions is necessary and a high degree of vacuum must be maintained in the refrigerator. This favours the entrance of air through the joints and stuffing-box, and the efficiency of the machine is proportionately reduced. Again, under the action of repeated vapourisations and compressions commercial ether becomes acidified and converted into less volatile bodies, so that the charge has occasionally to be withdrawn and replaced by fresh ether, the old charge being rectified from these substances and from the lubricating materials employed in the air-pump. Taking all these things into consideration, I do not see how the fuel consumption can be less than double that employed in the best system, and the cooling water must be excessive, though probably not so much as with cold-air machines.

The Pictet machine which I saw was certainly doing good work; for a large ice production its size was moderate, and, as I have already mentioned, the compressor pumps were about one-fourth of the capacity of the ether machine. It had, however, in my opinion, two faults:—The nature of the medium used compelled the employment of copper in the construction of the compressor, condenser, refrigerator, and all parts in contact with the medium, which is sulphurous anhydride. This makes the first cost greater than it need be if iron could be used instead. Then, again, the vacuum side of the system was below the ordinary atmospheric pressure, so that the tendency of air and moisture to leak in and so form sulphuric acid, was a point to be considered, seeing that sulphuric acid attacks all metals. Another point, and one which certainly weighed with me, was that the heat of the compression-cylinder was very great, and this was kept cool by a constant stream of water running through a surrounding jacket, the piston-rod being also kept cool by means of a stream of water. Perhaps this matter may be a small one, but I was anxious to strip any machine or system selected of all its complications.

Having now found faults with all existing systems and with all media save ammonia, I next came to consider refrigerating by means of the compression of ammonia. Several different machines were in the market working on this plan, but I had only the opportunity of seeing one at work. An inspection of the table will show that ammonia vapour has a very high latent heat, and on this account, as well as its low boiling point, a small compressor only is necessary; this, of course, enables a smaller piston-rod to be used, and there is consequently less friction to be overcome by mechanical work. On the other hand, high vapour tension means high pressures on the compression side of the machine, and a consequent escape of ammonia if all joints are not perfectly made. The physical side of the question being satisfactorily settled, it seemed to me the only point to inquire deeply into was the actual mechanical construction of the machine.

On account of the corrosive action of ammonia upon copper, gun-metal, brass, etc., none of these metals or alloys can be used in the construction of an ammonia machine, and consequently they are made in every part of cast and wrought iron. On the condenser side of the system which I inspected the pressure was ten atmospheres, and about two atmospheres on the refrigerator side, which showed at once the necessity of good sound castings, of perfect joints, good flat flanches, and lastly, of a good stuffing-box and gland for the compressor piston-rod. I did not despair that those conditions could be realised in practice. I fully saw that if the compression system was adopted, then ammonia was the best medium to be used, and that if ammonia was employed then only the very best workmanship was allowable.

When I saw the Linde machine at work at the Wrexham Lager Beer Brewery, the faultless character of the workmanship was easily discernible, and I had no hesitation in finally selecting the Linde machine. Then came the question of the size required. I had calculated that when fully at work we should require cold, equal to a flow of brine, of 1000 gallons per hour, to be cooled from 19° C. to 8° C., and this means a size of machine capable of producing six tons of ice every 24 hours, or a cooling power (not making ice) equal to ten tons. In this machine, the joints between the ends of the wrought-iron piping and the flanges were all carefully tinned and soldered with pure tin, the joints between two flanges being made with the thinnest sheet indiarubber obtainable. The gland and stuffing-box to the compressor-piston is very long and of peculiar construction, and it acts so perfectly that even in the hot weather, when the pressure has risen to 12 atmospheres owing to the warmth of the cooling water in the condenser, there is only the faintest smell of ammonia in the room. In fact, during the whole time it has been working the loss of ammonia for making 1800 tons of ice has only been £3 10s. The compression cylinder works perfectly cold without possessing any water-jacket or similar contrivance, and is even partially covered with frost when working at low brine temperatures. The fuel account also shows that the available coal heat passed into the steam engine has produced 9 tons of ice per ton of coal actually used. This is much lower than the efficiency reached at the Munich trial; but our steam boilers are not of the best construction, and as the result of several years' work with German machines, with coal evaporating 6lb. of water per lb. of fuel, it has been found that in a 24-ton machine 1 ton of coal will make 14 tons of ice, and in a larger machine—viz., a 48-ton capacity—1 ton of coal will produce nearly 16 tons of ice, including the pumping of water and driving all shafting.

The report on one of these machines, published by the Polytechnic Institution of Civil Engineers in Munich, stated 26lb. of ice produced per lb. of fuel, but this is a result which could not be sustained in practice without the condenser and refrigerator surfaces were considerably extended, and then that again would add to the cost of the plant.

After the working of this plant as a refrigerator for the cooling of oils and gas in my patented process, by the circulation of cold brine for many months, the low price of benzol compelled me to close the carbonising process in May last, and during last summer and autumn I manufactured ice and supplied Sheffield and the surrounding towns with it. Water identical with the Sheffield water supply was placed in moulds 6½in. square and about 3ft. long or deep, these blocks when frozen weighing about half-a-hundredweight. Keeping the brine at —8° C. and in good circulation these moulds would freeze solid in 8 hours, but with deficient circulation and the brine entering at —16° C. and leaving at —2° C. they would take 24 hours, thus in ice making it is clearly shown that T*h* and T*l* must approach each other very closely and a large volume circulated.

The ice produced by the process of freezing still water is opaque owing to the air enclosed in it; a bubble of air (or thousands of bubbles) is mechanically squeezed out near the side of the mould, and it attaches itself to the advancing ice in such a manner as to leave a capillary tube running from the outside to the very core of the mould.

When selling the half cwt. blocks we had many complaints of their melting too rapidly, and as this was I thought due to the smallness of their size, I arranged moulds to hold one cwt. 13in. by 6½in. by about 3ft. deep. I expected these to freeze in the same time as the 6½ square blocks, but in this I was wonderfully deceived. My notion was that the heat (or cold) would only have to strike across 3¼in. in each case, the line of least resistance so to speak, but in actual practice these moulds took half as long again to freeze. Hotels and fishmongers still complained of this opaque ice, though we were enterprising enough to secure their custom by freezing lobsters, salmon, etc., etc., in the centre of blocks for them The elimination of the air is not an easy problem in an improvised plant like ours; it is easily done by agitation during freezing, but with us that was hardly possible. Eventually I made the two kinds, clear and opaque, the former by inserting a small tube down the centre of each mould and by connecting it with an air compressor, which kept a small stream of air bubbling through.

The question of the rapidity of melting was an important one, and after much investigation I have come to the conclusion that in air melting, the opacity has very little to do with it. I have on several occasions exposed one cwt. blocks of clear ice (made by blowing air through it while freezing), opaque ice (made by freezing still water) and Wenham Lake ice, both out of doors and under cover, and in all cases the last few ounces were all on the plank together, but two half cwt. blocks will disappear long before a single cwt. In fact the single cwts. disappeared in 42 hours, the half cwts. in 22 hours.

When immersed in water, opaque ice will melt much sooner than clear ice, but of course it does more cooling work, and if water is to be cooled by running it through blocks of ice in a tank, as is done in some breweries, it should be run much quicker through opaque ice than through clear. But refrigeration by means of solid ice is much more costly than by means of a refrigerating machine, as a machine, when taxed to its utmost to produce six tons of ice daily, will do cooling equal to 10 tons of ice.

Another interesting fact forced itself upon my attention during the manufacture of ice, and that was that in freezing, the soluble constituents of the water were gradually forced into the centre of the mould, so that when the last quart of water remaining unfrozen was poured out, this would contain the whole, or nearly so, of the soluble impurities.

The water used for ice-making contained 8·2 grains of total solid matter per gallon, a piece of the clear ice melted contained 1·2 grains per gallon of total solids, while the residual unfrozen water in the centre of the moulds contained 264 grains per gallon.

As to the cost of making ice and delivering it to customers much may be said. One reads in print very often that by such and such a machine ice can be made at 5s. or even 3s. 9d. per ton. I will not ask you to doubt such statements, but I will say, do not build up too many hopes upon them. Ice is not like cast iron, and if you wish to store it you must have some very expensive buildings. About seven per cent. of the make will be lost in storing; if you deliver it to customers in two ton lots and are at a distance from them, the loss will be 10 per cent.; while if a retail trade is done, the loss will be 33 per cent. at least. I have come to the conclusion that without the machine is a very large one, and worked to its full capacity, ice cannot be sold wholesale under £1 per ton to leave a profit, if it has to be delivered to customers.

With refrigeration merely it is different, and I have little doubt but that cooling could be done for 5s. per ton of ice equivalent, on a six ton machine, and therefore I am surprised this system has not found its way much more into chemical manufacturing than it has at present in England.

On the Continent the aniline-colour works use very large machines, some of which I saw when amongst them in March last. They are used in the manufacture of sulphuric acid, carbolic acid, chlorate of soda, in the manufacture of best sugar by the strontium process, in distilleries, in stearine works, chocolate manufacture, dairies and in candle works. It is a matter of very simple calculation whether water cooling or refrigeration is most effective, and it very often happens that a sufficiently low temperature cannot be reached by simple water cooling, especially in summer.

DISCUSSION.

The CHAIRMAN, after thanking Mr. Davis for his interesting paper, regretted that he had entirely omitted to refer to Pictet's latest machine, and "Pictet's Fluid," when comparing critically the various systems applied to the manufacture of artificial cold. Mr. Levinstein's experience with a Linde ice machine, which extended over five years, led him to substantially confirm Mr. Davis's statements with regard to its general efficiency. The fact, however, must not be overlooked that such a machine was very costly, and it therefore became a very serious matter to those who wished to put an ice machine down what system ought to be adopted, and he was not at all prepared to say that Linde's machine was still the best, or superior to all other machines. One ought not rashly to jump to conclusions without accurate knowledge of all the other systems, and if he had to put another ice machine down he would certainly very carefully examine Pictet's latest machine, which appeared to him to possess in some respects advantages over Linde's machine. As far as he was informed, the Pure Ice Company, in Liverpool, and also the Glaciarum, in Southport, had recently altered their machines according to Pictet's latest improvements, and these were also working satisfactorily with Pictet's Fluid. He only mentioned these facts in order to show that Pictet's Fluid was already successfully used in their neighbourhood by artificial ice manufacturers, and he thought that it would have been very interesting to have heard Mr. Davis's opinion about Pictet's latest machine, and also about Pictet's Fluid. This "fluid" possessed very singular properties. Its vapour tension considerably deviated from what might have been theoretically expected. It was produced by compressing a mixture of carbon dioxide and sulphur dioxide. As promised, he now appended a table showing the comparative vapour tension at various temperatures of sulphur dioxide, of the vapour tension, both actual and calculated, of Pictet's Fluid, and also of that of ammonia :—

Centigrade.	Pressure in Atmospheres.			Ammonia.
	Sulphurous Acid.	Pictet's Fluid calculated.	Pictet's Fluid actual.	
−30°	0·76	0·77	0·77	1·14
−25	0·55	0·91	0·89	1·15
−20	0·61	1·28	0·98	1·83
−15	0·76	1·59	1·18	2·28
−10	1·00	1·97	1·31	2·82
− 5	1·25	2·41	1·60	3·45
+ 0	1·51	2·93	1·83	4·19
+ 5	1·90	3·50	2·20	5·00
+10	2·35	4·21	2·55	6·02
+15	2·78	4·98	2·98	7·12
+20	3·30	5·88	3·40	8·40
+25	3·80	6·86	3·92	9·80
+30	4·60	8·00	4·15	11·11
+35	5·30	9·15	5·05	13·08
+40	6·20	10·10	5·72	15·29
+45	7·20	12·16	6·30	17·38
+50	8·30	13·98	6·86	19·98

The vapour tension, therefore, of Pictet's Fluid was comparatively high at low temperatures and comparatively low at high temperatures, which property was a desideratum in cold-producing agents. Pictet's Fluid was stated to possess fifty per cent. more effective power than pure sulphur dioxide.*

Mr. **Thomson** thought that Mr. Davis had not given sufficient prominence to the conditions under which different ice-making machines were tested. Much would depend upon the temperature of the air and water at the time the experiment was made as to what quantity any ice machine would produce per ton of coal consumed. Some ten years ago he suggested to Mr. Gamgee the use of anhydrous ammonia instead of sulphur dioxide for use in the Pictet machine, and he aided him in making an experiment with it, which had proved very successful; he understood, moreover, that Mr. Pictet afterwards patented the use of anhydrous ammonia to be used instead of sulphur dioxide. What he (Mr. Thomson) feared most, then, was that any escape of ammonia might prove serious to workmen from its powerful pungency, but to his surprise he found that having robbed ordinary aqueous ammonia of its water, the anhydrous substance no longer possessed very pungent qualities, and he found under such conditions it could be inspired in considerable quantity with comparative comfort. He did not remember to have seen any record of this property of anhydrous ammonia. The exceedingly pungent properties were again produced by passing the anhydrous gas into a little water, and thus thoroughly saturating it. Perhaps Mr. Davis had observed this, or could throw some light upon it? This might explain to some extent why very little smell of ammonia is detected from leakages in working the Linde machine. Another point raised in the paper was the action of ammonia on iron. Could Mr. Davis give any explanation of the way in which ammonia acted on iron? One could understand that ammonia in gas works, which contained ammonium sulphide, might corrode iron, from the action of the sulphur, but it was more difficult to comprehend what could be the action of aqueous ammonia on it. Again, Mr. Davis mentioned that sulphur dioxide acted on iron, whilst copper was not acted on by it. He remembered about ten years ago speaking to Mr. Pictet on this matter, and he was informed by him that the sulphur dioxide had no action whatever on iron, and the pumping cylinders and pistons of his machine were then made of iron or steel; perhaps Mr. Pictet had changed his mind on this point since then, and probably Mr. Davis could give some explanation as to this point, and why sulphur dioxide should act on iron and not on copper? because it was evident that if the action were due to the dioxide becoming converted into sulphuric acid, that acid one would assume would attack copper as well as iron.

Mr. **Irwin** inquired if Mr. Davis had calculated the amount of coal required to refrigerate a ton of water at 0° C.; also what would be the cost of the plant required to produce ten tons of ice weekly?

Mr. **Davis**, in reply, said that in his paper he had dealt with his experiences and convictions only, and had personally no experience with the new "Pictet liquid." In fact, he had purposely refrained from mentioning this liquid, as he was aware that a warm controversy was proceeding abroad between the Linde and the Pictet companies. In reply to Mr. Thomson, the formula given in the early part of the paper would fully explain the amounts of ice produced under varying temperatures, the temperature of the ambient air having but little to do with it. The temperature of the cooling water determined the working pressure and the pressure the steam engine had to overcome. He could not say theoretically what the reaction was between ammonia and wrought iron, but it only occurred at high temperatures in presence of steam. With regard to the action of sulphurous acid on iron, he had not studied that either, as all the sulphurous acid machines that he had seen were constructed of copper. The loss of seven per cent. of ice in storage was in storing and selling nearly as made; the sale of ice was not a regular trade, some days more could be sold than made, and on others more was made than could be sold, and the loss of seven per cent. occurred in restoring an equilibrium. In reply to Mr. Irwin, he had not calculated the coal required for a ton of ice, for the simple reason that it varied so much under different conditions, but in reply to his other question, he might say that the plant required for refrigerating ten tons of water to 0° C. daily would cost about £1000.

PROFESSOR BEDSON IN THE CHAIR.

ON NEW OR PERFECTED METHODS FOR THE DETECTION AND ESTIMATION OF ORGANIC BODIES, BASED UPON THEIR OXIDATION BY POTASSIUM PERMANGANATE.

BY JOHN HENRY SMITH, PH.D. (ZURICH),
Associate of the Royal College of Science, Dublin.

PART II.

Oxidation by MnO_2 in Acid Solution.

In the first part of this paper, it has been shown (Exp. 67) that no loss of oxygen occurs from the action of dilute sulphuric acid upon manganese dioxide, so long as no free permanganate is present. This observation, in conjunction with the fact to which we have called attention, that $KMnO_4$ can be reduced completely to MnO_2 by means of a manganous salt, renders the establishment of a method of oxidation by means of the dioxide a matter of comparative ease. We have seen (Exp. 2) that it is possible to reduce $KMnO_4$ to MnO_2 in a neutral solution, by using only the theoretical quantity of $MnSO_4$ to satisfy the equation—$K_2Mn_2O_8 + 3MnSO_4 + 2H_2O = 5MnO_2 + K_2SO_4 + 2H_2SO_4$. As the solution requires to be heated a considerable time before complete reduction is effected, and as the presence of a small excess of $MnSO_4$ is no detriment, it is preferable to effect the reduction at once with excess of $MnSO_4$. I find that an excess of 10cc. $n MnSO_4$ solution (*i.e.*, the theoretical amount required to precipitate 10cc. $n KMnO_4$) is ample to reduce the last trace of permanganate, with a couple of minutes' heating on the water-bath. A larger excess should be avoided, if a subsequent oxidation of the filtrate by $KMnO^4$ be contemplated, because whatever excess is left will appropriate its own equivalent of permanganate, which latter would consequently be unavailable for the further oxidation of the organic body.*

I find a solution of manganous sulphate, twice the normal strength, as defined above, to be most generally useful. It is made by dissolving 16·2grms. of the anhydrous salt in distilled water, and making up to 1 litre. The composition of the $MnSO_4$ employed must be carefully determined, as the salt crystallises with different amounts of water. That which I used was in the state of powder, and corresponded to the formula, $MnSO_4.H_2O$. To 50cc. $2 n KMnO_4$, contained in a 500cc. flask, 55cc. of the above solution are added. After heating for a minute or two on the water-bath, aided by gentle agitation, the solution will be found to be colourless. 10cc. $5 n H_2SO_4$ are then added, together with 50cc. *n*-organic solution, and the bulk made up to 250cc. The flask is then placed over a Bunsen burner, and the contents boiled gently for half-an-hour, the flame being increased towards the end of that time. The finely-divided MnO_2 becomes thus perfectly disseminated throughout the liquid, leaving nothing more to be desired in the matter of circulation. Although I have been able to oxidise oxalic acid completely on the water-bath, without any endeavour to promote circulation of the MnO_2; in the case of bodies more difficultly oxidisable, the full action of the dioxide is not experienced, unless means to promote the circulation of the precipitate be employed. I have ascertained that there is no loss of oxygen from the action of acid of this concentration upon the MnO_2, when the solution is maintained at actual ebullition. In a direct experiment (199), in which the solution was boiled briskly for half-an-hour, a loss of only 0·1cc. $n KMnO_4$ was observed, a quantity which comes within the ordinary errors of experiment.

After boiling, the solution is diluted considerably and filtered, and the precipitate washed with warm distilled water. It is advisable to wash the filter before use with a small quantity of hot dilute sulphuric acid. It is not necessary to wash the precipitate more than twice. If the washing be continued longer, or the wash water be too hot, a portion of the MnO_2 will be dissolved, rendering the experiment useless. Should a protracted washing be essential, then the wash water employed must be acidified.

After washing, the precipitate is washed down into the flask which it originally occupied, and dissolved, together with any MnO_2 adhering to the filter, in standard $FeSO_4$ solution, the excess of the latter being determined by titrating back with $KMnO_4$. A normal solution of $FeSO_4$, containing the equivalent of twice normal free H_2SO_4, I find very convenient for dissolving this precipitate, as well as for general purposes. The value of the precipitate, obtained in terms of $KMnO_4$, deducted from the original $KMnO_4$ added, gives the equivalent of MnO_2 reduced by the organic body under investigation.

In experiments with oxalic acid, both heated on the water-bath and boiled over a Bunsen burner, the filtrates failed to produce a further reduction of $KMnO_4$, and in the case of the latter (200) the MnO_2 reduced corresponded exactly to the complete oxidation of the acid.

After I have subjected a sufficient number of exemplary bodies to a thorough investigation, by means of this and the other processes which I have devised, I intend to tabulate the whole of the results and bring them before the notice of this Society; and I anticipate we will be able to recognise certain relationships existing between the constitution of those bodies and their susceptibility to oxidation by $KMnO_4$ and MnO_2 under varying standard conditions.

With regard to the filtrate, it may be further subjected to oxidation by $KMnO_4$. It is advisable to employ 75cc. $2n KMnO_4$ for this purpose, making up to 750cc., and giving one hour's heating. Before adding the $FePO_4$ solution, the filtrate should be neutralised with 10cc. $5n NaHO$. In all probability, the $KMnO_4$ reduced by the filtrate

---

* On the whole, it is preferable to get rid of the excess of $MnSO_4$ and free acid by filtration.

would correspond to the difference between the total amount reduced by the body, and the amount equivalent to the MnO_2 reduced. It is of course possible that a very volatile body might be formed by the oxidation with MnO_2, or a body incapable of oxidation by $KMnO_4$, but not itself produced by direct oxidation with permanganate. I should consider that these cases, and more especially the latter, would very rarely occur. In any case such an irregularity could be easily detected by the oxidation of the filtrate.

OXIDATION BY $KMnO_4$ IN ALKALINE SOLUTIONS.

Great difficulty was experienced in working out a method adapted to the estimation of the amount of permanganate reduced by organic bodies in alkaline solution. The method which most naturally suggested itself—*i.e.*, of adding excess of acidified $FeSO_4$ after the oxidation is complete, and titrating back with $KMnO_4$—is altogether unreliable. Even could further oxidation during the mixing of the liquids be prevented by adding the alkaline solution *very slowly* into a *large excess* of strongly acidified $FeSO_4$, there is still the probability of too great a quantity of $KMnO_4$ being absorbed in titrating back (even should the solution be quite cold during titration) on account of the large quantity of $MnSO_4$ present in the solution, which we found to be a great accelerator of the speed of oxidation in direct titrations. This source of error becomes all the more serious when we consider that oxalic acid, which we know to be a very frequent product of oxidation in alkaline solutions, is one of the organic bodies most easy of oxidation by $KMnO_4$ in acid solution. I considered, therefore, that the most certain test of the accuracy of such a method as I was hoping to establish, would be that it should indicate no reduction of permanganate with pure oxalic acid. Bertholet* states that oxalic acid is oxidised slowly to CO_2 and H_2O in alkaline solutions; but, as we shall see later on, this is not the case, at least not to any appreciable extent.

In order to determine whether any loss of oxygen occurs when $KMnO_4$ is heated in alkaline solution, as maintained by Jones,† the following experiments were made:—To 50cc. $nKMnO_4$, 50cc. n-alkali were added, the bulk made up to 250 with distilled water, and heated on the water-bath. After heating, excess of standard $FeSO_4$ was added, and the excess titrated back with $KMnO_4$. The results are given below:—

No. of Experiment—	201	202	203	204	205
Alkali added	KHO	K_2CO_3	KHO	K_2CO_3	$KHCO_3$
Length of heating	½hr.	¾hr.	3hrs.	3hrs.	3hrs.
Loss = cc. $nKMnO_4$ ..	0·3	0·9	0·1	0·9	0·2

These experiments show that the alkalis contained impurity oxidisable by $KMnO_4$; but no loss of oxygen occurs, since after three hours' heating practically no greater loss is experienced than after only half or three-quarters of an hour's heating. To confirm the presence of these impurities, 50cc. of the normal alkalis were acidified and titrated directly with $KMnO_4$ at a temperature approaching ebullition; while to other equal quantities excess of H_2SO_4 (free from oxidisable impurity) was added, together with 50cc. $nKMnO_4$, and the solution, made up to 250cc., heated for three hours on the water-bath. The following results were obtained:—

No. of Experiment—	206	207	208	209	210
Alkali added	KHO	KHO	K_2CO_3	K_2CO_3	$KHCO_3$
cc. nH_2SO_4 added	100	100	100	100	100
cc. $nKMnO_4$ lost......	0	0·25	0·2	0·25	0
	cold	boiling	cold	boiling	boiling

Direct titrations.

No. of Experiment—	211	212	213	214
Alkali added	none	KHO	K_2CO_3	$KHCO_3$
cc. nH_2SO_4 added	50	100	100	100
cc. $nKMnO_4$ lost......	0·7	1·25	1·65	0·8
cc. $nKMnO_4$ lost, after deducting result of 211	—	0·55	0·95	0·1

Here it is seen we have sufficient impurity in the alkalis to account for the loss we had observed. As the impurity is only partially and difficultly oxidised in direct titration, it is probably of organic nature, and oxidised to oxalic acid by permanganate in alkaline solutions, since the numbers obtained in these solutions (Experiments 203 and 204) agree very closely with the above. It is evident, therefore, that unless the impurity in the alkalis be estimated and allowed for, serious errors might be introduced; but none need be feared from actual evolution of oxygen in alkaline solutions under the conditions existing. Other samples of alkalis gave the following results:—

No. of Experiment—	215	216	217	218	219
Alkali used	NaHO	K_2CO_3	$KHCO_3$	NaHO	NaHO
cc. nH_2SO_4 added	125	125	125	none	$MnSO_4$ added
cc. $nKMnO_4$ lost after deducting error	0·1	0·2	0·5	0·1	0·1

Considerable difference exists, therefore, in the oxidisable impurity of different samples of alkali. It is probable that the sodium alkalis will be more generally pure in this respect than those of potassium. In Experiment 218 the solution was boiled briskly for half-an-hour with 50cc. $nKMnO_4$, but still no greater loss was experienced than that due to the impurity in the NaHO. The same result was yielded in Experiment 219, in which one-half of the $KMnO_4$ had been precipitated as MnO_2 by $MnSO_4$ before heating. There is no loss, therefore, from the mutual action of MnO_2 and $KMnO_4$ in alkaline solutions, as there is in acid ones.

The next method which suggested itself for the estimation of the oxidation occurring in alkaline solutions, was to filter the solution through asbestos or glass-wool after the oxidation was complete, and determine the amount of MnO_2 remaining on the filter after washing the same. The following experiments were, therefore, instituted with the double object of testing this method and of ascertaining the possibility of utilising the same for the estimation of manganous salts. A solution of manganous sulphate, whose strength had been accurately determined, or one formed by the exact titration of acidified oxalic acid, was added to a warm solution of $KMnO_4$,

---

* Jahresb. 1867, p. 331.

† J. Chem. Soc., 1878, p. 95.

previously made sufficiently alkaline with NaHO that after mixing 20cc. n-alkali would remain free. After heating on the water-bath the bulk was made up to 500cc., and the remaining $KMnO_4$ determined in an aliquot part of the filtrate. The MnO_2 on the filter after washing was also estimated as a check. The solution was filtered through glass-wool free from oxidisable impurity. The following are the results :—

No. of Experiment—	220	221	222
cc. $nKMnO_4$ employed	100	200	100
Addition	Titrated Oxalic Acid	$MnSO_4$	$MnSO_4$
Time of heating	½hr.	½hr.	½hr.
cc. $nKMnO_4$ theoretically reduced	16·55	22·25	22·25
cc. $nKMnO_4$ actually reduced	18·1	27·25	25·75
% $MnSO_4$ indicated	109·3	122·5	115·7

We learn from these experiments that the amount of $KMnO_4$ retained by the precipitate after washing is so large as to render such a method quite impossible. As no loss of oxygen occurs, it is difficult to account for the precipitate containing so much more available oxygen than the calculated quantity. It may be that the $KMnO_4$ is mechanically held by the precipitate, or, I think it is more likely, that in an alkaline solution in presence of pre-existing MnO_2, $KMnO_4$ is further reduced to the same form, as it is in acid solution, but that the liberated oxygen, instead of being lost, forms some peroxide, which remains in solution. The following facts may be taken in support of this view :— An acid solution of $KMnO_4$ may be boiled over a naked flame without the slightest inconvenience. An acid solution containing precipitated MnO_2, but no free $KMnO_4$, may likewise be boiled with impunity ; but an acid solution containing both $KMnO_4$ and MnO_2 cannot be so boiled, or even on the sand-bath, without causing severe concussions of the liquid. In a similar manner $KMnO_4$ and MnO_2 may be boiled separately in an alkaline solution with perfect safety ; but if *both* be present the same concussions are produced. Now, I have referred in the first part of this paper to the chemical action which takes place in acid solution, in virtue of which oxygen is liberated and $KMnO_4$ reduced to MnO_2. Is it not exceedingly probable that this action is the cause of the incontrollable behaviour of the solution in *both* acid and alkaline solutions, but that in the latter oxygen, in place of being evolved, remains in solution as a peroxide ?

This filtration method having failed, it occurred to me to precipitate the whole of the free $KMnO_4$ remaining after the oxidation was complete by $MnSO_4$, to filter the alkaline solution, and, after washing the precipitate, to dissolve it in $FeSO_4$ and titrate back with $KMnO_4$. The difference between the amount of $KMnO_4$ equivalent to the precipitate and that originally added would, of course, be a measure of the oxygen obsorbed by the body under investigation.

With regard to the filtering medium, I was very anxious to dispense with the use of asbestos and glass-wool, chiefly on account of the long time taken up by the process when these bodies are used. The filtration through paper is, on the other hand, very rapid and very suitable for the purpose, more especially as the precipitate always contains a certain amount of MnO, which is liable to oxidation. The following experiments with various filters are interesting, as showing the effect of $KMnO_4$ and of the alkalis upon filtering paper and the conditions under which it may be used for filtration. In the first six experiments the solution employed contained 50cc. $nKMnO_4$, either neutral or with 50cc. nH_2SO_4 or KHO added. The total bulk was 250cc. in each case, and the solution was either filtered through cold, or heated for half-an-hour on the water-bath with a 7½-in. English filter. The results, which are only roughly comparative (as no Fe_23SO_4 or phosphate was present in the acid solution ; and the other solutions were treated with excess $FeSO_4$ immediately after oxidation), are here given :—

No. of Experiment—	223	224	225	226	227	228
State of solution	Acid	Alk.	Neut.	Acid	Alk.	Neut.
How applied	Passed through cold			Treated on water-bath		
cc. $nKMnO_4$ absorbed	1·55	5·25	0 5	32·75	43·75	17·75

In Experiments 226 and 227 we see that the reduction to MnO_2 has been complete. The largely-increased oxidation in alkaline solution should be noted, it being due, of course, to the solvent action of the alkali upon the material of the filter.

To determine the action of the alkalis alone upon the filters, the following series of experiments was undertaken. In each case the solution, made up to about 300cc., was filtered four or five times at a temperature of 80° to 90° C. through a 7½-in. English filter. The solutions were then acidified, and the organic matter dissolved, either wholly oxidised by excess of $KMnO_4$ in the usual manner, or merely titrated directly at boiling temperature :—

No. of Experiment—	229	230	231
cc. n-Alkali employed	100KHO	$100K_2CO_3$	$100KHCO_3$
How estimated	With excess $KMnO_4$		
cc. $nKMnO_4$ absorbed, after deducting impurity	3·4	2·0	1·1

No. of Experiment—	232	233	234
cc. n-Alkali employed	50KHO	$50K_2CO_3$	$50KHCO_3$
How estimated	By direct titration		
cc. $nKMnO_4$ absorbed, after deducting impurity	0·1	0·15	0·1

The above experiments show that the filtrates might be utilised, in the method contemplated, for direct titration without any serious error arising, but the error is too great to allow of their being subjected to complete oxidation with excess of $KMnO_4$. As might be expected, the solvent action is greatest in the case of KHO, and least in the case of KHCO .

The next series shows the influence of various qualities of filters. 100cc. nNaHO were employed, and passed two or three times through the filter at a temperature near boiling point. After the treatment the solution was rendered acid, and the $FePO_4$ solution added with the $KMnO_4$ as usual. The bulk was made up to 250cc., and heated half-an-hour. The filters were all 5½in. in diameter. The last three experiments show the effect of a second, but exactly similar, treatment of the same filters.

No. of Experiment—	235	236	237

cc. $nKMnO_4$ absorbed by organic matter dissolved....	2·0	1·2	2·5

No. of Experiment—	238	239	240
Quality of Filter	English	Swedish	Schleicher's Washed
cc. $nKMnO_4$ absorbed by organic matter dissolved....	0·1	0	0·5

These experiments show us that the filtrates in the method under consideration might be made available for subsequent oxidation in acid solution with excess of $KMnO_4$, when paper filters are employed which have received a preliminary washing with boiling normal alkali. The second treatment with boiling normal alkali, which was given in the above experiments, is really a much more severe test than they would be required to stand in practice, as the solution would be much more dilute and not quite so hot. At the same time, it is much preferable to employ the cheaper filters, more especially as they are really superior for this purpose.

Of course, it will be understood that the action of the alkali upon the filter does not absolutely stop after this preliminary treatment, but that the superficial or more easily oxidisable portions of the filter are withdrawn by the process. The following experiment (241) will show that the solution of the filter by the alkali is a continual process. Six of Schleicher's washed filters, 5½in. diameter, were boiled with 100cc. nNaHO for half-an-hour. The solution was then neutralised and filtered, and excess of $KMnO_4$, together with 20cc. of the acidified $FePO_4$ solution added. The solution was then heated for one hour. 128·8cc. $nKMnO_4$ had been absorbed by the solution. After treating the same filters, previously well washed, a second time in exactly the same manner, 129·4cc. $KMnO_4$ were required by the solution. After a third treatment 72cc. $nKMnO_4$ were absorbed. It is instructive to note that oxalic acid could only have formed a small portion of the dissolved organic matter, because the last solution obtained only absorbed 12cc. $nKMnO_4$ by direct titration in a hot acid solution—*i.e.*, only one-sixth of the total $KMnO_4$ required.

From Experiments 12 to 16 we learned that MnO is continually oxidised to MnO_2 by atmospheric oxygen. The oxidation naturally diminishes in intensity as the amount of the lower oxide decreases and that of the higher oxide increases. The error introduced by this oxidation is very small, if only the least possible excess of $MnSO_4$ to precipitate the whole of the free $KMnO_4$ be added, and the filtration be executed as rapidly as practicable; but I was anxious to check this oxidation altogether if possible. Although I was not successful in achieving this object, a short account of my experiments in this direction may save others the trouble of going over the same ground again.

The general conditions of working were as follows:—To 50cc. $nKMnO_4$ 50cc. n-alkali were added. The total bulk was made up to 250cc., and the solution heated for half-an-hour on the water-bath. In order to magnify the error arising from the oxidation of the atmosphere, the $MnSO_4$ solution was added in much larger quantity (50% excess) than that actually required for precipitation of the $KMnO_4$. The solution, after being well shaken, became colourless almost immediately. It was then filtered, and the precipitate washed as rapidly as possible. The funnel was then transferred to the flask in which the precipitate had been formed, and the latter washed down into the flask with hot water. The precipitate, and any MnO_2 adhering to the filter, were then dissolved in excess of strongly acidified normal $FeSO_4$ solution, and the excess titrated back with $KMnO_4$ in the usual manner. When oxalic acid was added in the experiment, the filtrate was also estimated by direct titration, after acidifying with H_2SO_4. As a rule, parallel experiments were made with all three forms of alkali—viz., caustic, carbonate, and acid carbonate, in order to find which was the most preferable to employ. The filtration proceeded very rapidly through English filtering paper, and one's whole time was employed in attending to the filtering entailed by three parallel experiments. In the following tables some average results of these experiments are given:—

No. of Experiment.	Alkali added.	cc. $nKMnO_4$ equivalent to O gained.	REMARKS.
212	KHO	1·65	
213	Do. (10cc. n)	1·85	No decreased oxidation with less alkali.
214	KHO	1·0	Added dilute H_2SO_4 to the precipitate on filter as soon as solution had passed through.
215	K_2CO_3	0·8	Less oxidation than with KHO.
216	,,	0·7	Washed precipitate with dilute H_2SO_4 on filter.
247	$KHCO_3$	0·4	Less oxidation than with K_2CO_3.
248	,,	0	Washed precipitate with dilute H_2SO_4
249	,,	0	50cc. n-oxalic acid added; washed with acid; filtrate had lost 3·3cc. n-oxalic acid.
250	$NaHCO_3$	0·1	Similar to 248; washed with acid.
251	,,	0	Oxalic acid added; 3·3 cc. deficient in filtrate; washed precipitate with acid.

As might have been expected, the addition of acid to the precipitate checks the atmospheric oxidation to some extent. It is very doubtful, however, if such a course could be adopted in practice. The only advantage which could be gained by its employment would be in the case of the addition of the acid before the precipitate had been thoroughly washed, and under such conditions the probability is that even with cold acid the organic body under investigation would be oxidised by the MnO_2 in contact with it. Experiments 249 and 251 confirm this view in the case of oxalic acid.

The very slight atmospheric oxidation with the acid carbonate should be noted. The difference in the behaviour of the three alkalis was rendered visible by precipitating simultaneously equal volumes of manganous sulphate solution with equivalent quantities of KHO, K_2CO_3, and $NaHCO_3$ respectively. The first two precipitates turned brown almost immediately, while the last (doubtless a bicarbonate of manganese) remained perfectly white after being exposed to the atmosphere a whole day. That the oxidation is much more active in the case of the caustic alkali than with the carbonate, was shown by the precipitate with the former finally turning black, while that with the latter remained brown in colour.

In experiments with caustic alkali, in which variations were made in the order in which the solutions were mixed, it was found that the gain from atmospheric oxidation was much less when the alkali was added *after* mixing the $KMnO_4$ and $MnSO_4$. This was no doubt due to the formation of a large bulk of MnO_2 in the first instance, while in the presence of alkali a large quantity of MnO would be naturally formed initially, which would be subjected to partial oxidation by the atmosphere before being completely oxidised by the $KMnO_4$ present. As a matter of fact, hardly any less gain was experienced when the $MnSO_4$ was precipitated with KHO, and *then* $KMnO_4$ added, than when sulphate was added to the *alkaline* permanganate. Although $MnSO_4$ must be the final addition in practice, we may infer that an advantage would be experienced by adding it *slowly*, and I find in practice that less of the solution is required when this precaution is attended to.

In the next series of experiments 50cc. *n*-oxalic acid were employed. The first four were precipitated with 50 per cent. excess $MnSO_4$, after heating a quarter of an hour only, while the last four were heated for four and a-half hours, and precipitated with the least possible amount of $MnSO_4$ solution.

No. of Experiment.	Alkali employed.	cc. $nKMnO_4$ = Oxalate deficient in Filtrate.	cc. $nKMnO_4$ = Actual Gain or Loss of O.	REMARKS.
252	KHO	0·1	2·1 gain	Oxalate nearly completely washed out.
253	K_2CO_3	0·4	1·0 ,,	Oxalate not so completely washed out.
254	$KHCO_3$	3·4	0·1 ,,	Large deficiency of oxalate in filtrate.
255	Ditto 33cc. *n*	5·4	0·2 loss	Still larger ditto.
256	KHO	0·4	0·3 gain	Much less atmospheric oxidation than 252 with more $MnSO_4$ added.
257	K_2CO_3	1·2	0·1 loss	Greater deficiency of oxalate than 253.
258	$KHCO_3$	3·65	0·35 ,,	No more oxalate deficient than with only quarter of an hour's heating.
259	Ditto 33cc. *n*	5·25	0·3 ,,	

These experiments are a further confirmation of the less liability of the precipitate in acid carbonate solution to oxidation. The beneficial influence of adding only sufficient $MnSO_4$ to effect the precipitation is very marked in Experiments 256 and 257. In the case of the carbonates, we find there is a great tendency to the precipitation of the oxalate. That this is a *mere precipitation*, and not an actual oxidation of the oxalate, may be inferred from the experiments with bicarbonate: after four and a half hours' heating we find there is no greater deficiency in the filtrate than after only a quarter of an hour's heating.

It is worthy of remark that the precipitation seems to occur during heating, and is apparently accompanied by MnO_2, without any loss of oxygen, however. Additional evidence is here presented by the experiments with the long heating, that no absolute evolution of oxygen takes place—at least, not with KHO or K_2CO_3.

As the bicarbonate precipitate is practically not oxidised by the atmosphere, it seemed advisable to endeavour to render this alkali available by adopting means to remove the oxalate adhering to the precipitate. The next experiments were made in this direction; 50 per cent. excess $MnSO_4$ solution being added as before. The following table exhibits the average results obtained:—

No. of Experiment.	Length of heating.	cc. $nKMnO_4$ = Oxalate deficient in Filtrate after— 1st Washing.	cc. $nKMnO_4$ = Oxalate deficient in Filtrate after— 2nd Washing.	Total Gain or Loss of Oxygen.	REMARKS. Second Washing of Precipitates with—
260	½hr.	4·6	3·1	0·2 gain	Strongly ammoniacal solution of $(NH_4)_2SO_4$.
261	,,	4·3	3·5	0·3 loss	Strong solution of NH_4Cl.
262	,,	4·1	2·8	0·1 gain	Strong solution of ammonium carbonate.
263	,,	1·1	3·6	0	Hot normal acetic acid.
264	¾hr.	3·4	2·1	0·5 gain	Ammonia water.
265	,,	2·0	2·0	1·4 ,,	Added 25cc. strong NH_4HO before filtering, and washed with ammonia water.
266	,,	2·4	—	1·25 ,,	Added 50cc. nNH_4HO after precipitation, but before filtering.
267	½hr.	4·5	—	0·5 ,,	Gave ½hr. extra heating with 200cc. nNH_4Cl.
268	,,	1·75	—	0·7 ,,	After precipitation added — 400cc. nNH_4HO + 400cc. $n(NH_4)_2SO_4$
269	,,	1·95	—	0·2 ,,	400cc. nNH_4HO + 400cc. nNH_4Cl.
270	,,	4·15	—	0·05 loss	Washed with hot nH_2SO_4 on filter.
271	,,	2·3	—	0·5 gain	Added 100 nNH_4HO + 10grms. NH_4Cl, before the $MnSO_4$.
272	,,	2·1	—	0·2 loss	Immediately after heating, added more than sufficient Na_2HPO_4 to precipitate excess $MnSO_4$.
273	,,	0	—	0·2 ,,	Like 272, but no oxalate present.
274	,,	2·4	—	0·3 ,,	Like 272, but phosphate added before heating.
275	,,	0	—	0·2 ,,	Like 274, but no oxalate present.
276	,,	1·9	—	0·4 ,,	Added more than sufficient Na_2HPO_4 to precipitate all the $MnSO_4$ subsequently added.

As a general result, we learn from these experiments that a certain portion (about ½) of the precipitated oxalic acid may be washed out by solutions containing free ammonia. The advantage gained in this respect is, however, more than counterbalanced by the fact of a considerable amount of atmospheric oxygen being absorbed by the precipitate, after treatment with the ammoniacal solution. This oxidation may be readily observed by treating the white precipitate formed by the addition of excess of $KHCO_3$ to $MnSO_4$ with ammonia, when it will turn of a brown colour at once, owing to the decomposition of the acid carbonate of manganese with formation of

MnH_2O_2, which is further oxidised without delay. When accompanied by NH_4Cl, the oxidation of the precipitate is considerably checked (269), but the same result may be more easily obtained by the simple addition of sodium phosphate to the solution, preferably before the addition of $MnSO_4$ (276). In that case only about half of the oxalate which would otherwise be held by the precipitate remains fixed. The phosphate was added in the hope that the formation of the oxalate precipitate, if it consisted of MnC_2O_4, might be altogether prevented, in favour of the production of the more stable manganese phosphate.

The reason why the addition of ammonium chloride prevents the oxidation of the precipitate to a great extent is due, I think, to the formation of an oxychloride of manganese. In all cases in which the chloride was employed, I observed, on dissolving the precipitate in $FeSO_4$, a finely divided white precipitate suspended in the solution, which was quite insoluble in acid solution even on heating. No similar precipitate was obtained with $(NH_4)_2SO_4$, or any other salts made use of.

The bicarbonate having thus failed to yield satisfactory results, I was led to return to the other alkalis. The following table shows the results of my endeavours to reduce the atmospheric oxidation, which had been experienced with KHO and K_2CO_3. The heating lasted half-an-hour, other conditions being also normal :—

No. of Experiment.	Alkali employed.	cc. $n KMnO_4$ = Oxalate deficient in Filtrate.	cc. $n KMnO_4$ = Total Gain of Oxygen.	Remarks.
277	KHO	0·6	1·75	No addition.
278	,,	0·3	2·1	Added sufficient Na_2HPO_4 to precipitate all $MnSO_4$ subsequently added.
279	,,	0·5	1·8	Added 40cc. $n H_2SO_4$ and large excess of Na_2HPO_4.
280	,,	0·5	0·25	Added 20grms. NH_4Cl after the addition of $MnSO_4$.
281	K_2CO_3	0·8	0·85	No addition.
282	,,	0·6	0·4	Na_2HPO_4 added before $MnSO_4$.
283	,,	1·2	0·5	10grms. NH_4Cl added immediately after the $MnSO_4$.

It will be seen that the ammonium chloride is very effective in checking the atmospheric oxidation, both in the caustic solution and that made alkaline with K_2CO_3. It seems, however, to prevent the solution of the oxalate precipitated with the MnO_2 in the case of the carbonate (283). The addition of phosphate seems also to have a slight advantage, in reducing the atmospheric oxidation when the carbonate is employed.

I next tried the effect of rendering the solution nearly neutral, just before precipitating with $MnSO_4$; but the results were again unsatisfactory. In an experiment (284) in which acid was added to the solution after heating, sufficient to leave only 3cc. n-free alkali after the addition of $MnSO_4$, 1·0cc. of the oxalic acid was retained by the precipitate, and a gain of oxygen equivalent to 0·8cc. $n KMnO_4$ was affected by the latter. The gain of oxygen was therefore not much diminished by this means, while the amount of oxalic acid retained by the precipitate was materially increased.

In point of fact, the KHO has the same effect of preventing the precipitation of the oxalic acid which we found ammonia to possess. In the next experiments, therefore, additional alkali was added, just before precipitation by $MnSO_4$. Only *twenty-five per cent. excess* $MnSO_4$ was added, but in other respects the normal conditions obtained. The results are here tabulated—

No. of Experiment.	Alkali used.	cc. $n KMnO_4$ = Oxalate deficient in Filtrate.	cc. $n KMnO_4$ = Total Gain or Loss.	Remarks.
285	KHO	0·25	0·9 gain	One hour's heating.
286	,,	0	0·1 ,,	,, ,, ,, Sufficient $KHCO_3$ added to form completely K_2CO_3.
287	,,	0·7	0	Added 10grms. NH_4Cl after the $MnSO_4$.
288	,,	0·05	1·1 gain	Added 50cc. nKHO just before $MnSO_4$.
289	K_2CO_3	0·4	0·25 loss	No addition.
290	,,	0	0·55 gain	Added Na_2HPO_4 sufficient to precipitate all the $MnSO_4$ subsequently added.
291	,,	0·15	0·15 ,,	Added 50cc. $n K_2CO_3$ just before $MnSO_4$.
292	$KHCO_3$	2·5	(?)	No addition.
293	,,	1·1	0·35 gain	Added just sufficient KHO to form K_2CO_3.
294	,,	0·25	0·1 loss	Added double the above quantity.

The addition of extra alkali has a marked effect in dissolving out, or preventing the precipitation of the oxalic acid along with MnO_2. Even in the case of the bicarbonate (294) we find the solution is nearly complete. Experiment 286 with KHO yields the best result, since the oxidation is diminished, as well as the oxalate being perfectly dissolved. The addition of NH_4Cl obviates the former error very satisfactorily, but increases the latter. The Na_2HPO_4 seems to have the reverse action on the carbonate; in fact, it appears to produce the same effect as free caustic alkali.

A few experiments were made with borax and potassium silicate solutions, in order to find if they would be likely to give more encouraging results than the sodium phosphate. The reverse was the case. The precipitates formed by these solutions with $MnSO_4$ are decomposed by free alkali even quicker than the precipitated phosphate, and turn brown or flesh-coloured almost immediately, owing to the oxidation of the MnO_2H_2 formed.

The only remaining resource seemed to be to employ as small an excess of $MnSO_4$ as possible, and to have plenty of MnO_2 present after precipitation, in order that the manganous hydrate might be protected from the atmosphere as far as practicable. Of course the difficulty might have been overcome by the use of elaborate and expensive apparatus, for filtering in an atmosphere free from oxygen, but I was anxious to avoid such complications as much as possible.

With regard to the amount of excess of $MnSO_4$ required to be added to obtain perfect discolouration of the solution, the following numbers give fair average results, obtained by the careful addition of the manganous salt to a boiling permanganate solution. The total bulk in each case was 250cc. :—

No. of Experiment—	295	296	297	298
State of solution ..	Neutral.	50 nH_2SO_4	50 nNaHO	11 nNaHO
cc. $nKMnO_4$ employed	50	50	50	100
excess $MnSO_4$ required	1	8—10	8—10	7—8

No. of Experiment—	299	300	301	302
State of solution ..	50 nNaHO	50 nNaHO + $ZnSO_4$	50 nK_2CO_3	50 $nKHCO_3$
cc. $nKMnO_4$ employed	100	100	100	100
excess $MnSO_4$ required	8—10	8·5	7—8	7—8

We learn from these experiments that the amount of excess of $MnSO_4$ bears a general ratio to the quantity of $KMnO_4$ precipitated. In neutral solutions, as we had already found (Experiment 2), a smaller excess is required than in either acid or alkaline ones; but if sufficient alkali be added to a neutral solution to neutralise the free H_2SO_4 liberated in the precipitation, as was done in Experiment 298, then the excess demanded is not much less than in the strongly alkaline solutions. With the carbonates, the amount of excess required is also somewhat diminished. There is no advantage in the addition of $ZnSO_4$ to the alkaline solutions, because, in Experiment 300, in which $ZnSO_4$ was added equivalent to the whole of the manganese precipitated, but before the addition of $MnSO_4$, exactly the same excess was required as in a parallel experiment without the addition of the zinc salt.

In the next experiments, the $MnSO_4$ was added very gradually, and the solution was well shaken after each addition, so that the least possible quantity should be used. The amount of $KMnO_4$ was also increased from 50cc. to 100cc. normal.

No. of Experiment.	Time of heating.	Alkali employed.	cc. $nKMnO_4$= Oxalate deficient in Filtrate.	cc. $nKMnO_4$= Total Gain or Loss.	REMARKS.
303	½hr.	NaHO	0·05	0·1 loss.	Only 50 KMO_4 and 50 oxalic acid added. $KHCO_3$ added to form K_2CO_3 completely.
304	½hr.	,,	0·3	0	$KHCO_3$ added as above
305	1hr.	100 nNaHO	0·05	0	No subsequent alkali added.
306	½hr.	,,	0	0·15 gain	Washed the precipitate longer. No subsequent alkali added.
307	½hr.	K_2CO_3	2·2	0	No further alkali added.
308	½hr.	,,	0·6	0·1 loss.	50 nK_2CO_3 added after precipitation.
309	1hr.	100 nK_2CO_3	0·6	0·2 loss.	No subsequent alkali.
310	½hr.	,,	0·7	0·4 loss.	No subsequent alkaii.
311	1hr.	$KHCO_3$	1·7	0·4 gain.	100 nNaHO added after precipitation.

We note that the larger amount of $KMnO_4$ employed, causes a larger proportion of the oxalate to be held by the precipitate, which is, of course, most conspicuous in the case of the carbonates. This may be obviated, however, to some extent, by increasing the quantity of free alkali, resulting, of course, in a greater tendency to oxidation of the precipitate.

In summing up the results of these experiments in alkaline solutions, it is very evident that the caustic alkali is the best to employ for the oxidation in question. Any advantage which the acid carbonate possesses, owing to the immunity of the precipitate formed in such solutions from atmospheric oxidation during filtration, is quite counterbalanced by the fact that such precipitate retains a considerable quantity of oxalic acid; and although oxalic acid might neither be present in the original solution or formed as a product of oxidation, still it is mostly probable that other organic salts would be held by the precipitate in the same manner. That the oxalic acid may be entirely dissolved out of the precipitate is no consolation whatever, because to do this would be to destroy altogether the only advantage which the use of this form of alkali presents. I am inclined to think that the full products of oxidation in alkaline solution wonld not always be obtained in the presence of acid carbonate, as this would probably form practically a neutral solution. Any additional source of information which this might otherwise have opened up to us, is, however, sealed on account of the liberation of CO_2 in the hot solution with formation of the normal carbonate. Even with the normal carbonate we would anticipate that a different stage of oxidation would sometimes be reached from that in a caustic solution. For experimental purposes its use might therefore be of considerable value. Such a large quantity of oxalic acid as we have employed would never actually be present in the ordinary course of working; and even the error due to this source may be removed by the addition of extra carbonate.

For practical purposes, however, the caustic alkali possesses the chief advantages. Before we can decide upon the best method for its application, and the best proportions to use, it will be well to consider the general conditions obtaining in actual working. When 100cc. $nKMnO_4$ are employed, if no oxidation of the organic body takes place, it is evident that the best mode of procedure would be similar to that adopted in Experiment 305 or 306; at least if any precipitation of the organic body with the MnO_2 was feared. We find that sufficient MnO_2 is present to protect the accompanying MnO from atmospheric oxidation. If an oxidation of the organic body occurred, however, the total quantity of MnO_2 after precipitation would, of course, be less than in the former case. At the same time there would be less of the organic body, or its product of oxidation, to precipitate. If the caustic alkali were left free in this case, as in Experiments 285 and 287, a considerable gain of oxygen would be the result; but if acid carbonate be added sufficient to form the normal carbonate, as in Experiments 286 and 303, then the error resnlting is inconsiderable. The error arising from employing this method in the presence of a larger amount of both MnO_2 and of oxalate, as in 304, is still less than that resulting from the employment of free alkali only, with the smaller quantity of dioxide, as a comparison with Experiment 285 will show. The method, therefore, which seems to recommend itself for all general purposes, is to increase the amount of caustic alkali from 50 to 75cc. normal, and convert it into the normal carbonate after the completion of the oxidation. By this means the error in 304 would be reduced. Indeed, this increase in the amount of alkali has a beneficial influence in another direction, as some bodies, such as glycerol, are only difficultly oxidised to their full extent, unless a large excess of alkali be present. I have now satisfied myself that many bodies are capable of reducing $KMnO_4$ to the form of Mn_2O_6 *only* in alkaline solution, and that the oxidation of the body may be completed in the *cold*, provided sufficient $KMnO_4$ be present. To employ such a large proportion (*i.e.*, three times as much as is required with reduction to MnO_2) would be very inconvenient ; but it is not necessary, since, in a boiling solution, the Mn_2O_6 is again split up into Mn_2O_7 and MnO_2. As this recuperation of the $KMnO_4$ is only *partial*, a *certain* excess of the latter is still necessary. The method which I have found most efficacious and economical is to add extra 25cc. $2nKMnO_4$ after a quarter of an hour's heating, should a considerable reduction appear to have been effected. This allows time for a substantial recovery of the first portion of $KMnO_4$ added, and provides fresh $KMnO_4$ for the oxidation of the last traces of the organic body.

The addition of the $MnSO_4$ solution is a matter of considerable importance. It should be added slowly, and the solution well shaken after each addition. With practice it will be seen, by the transparency of the solution after the precipitate has subsided, when the precipitation is nearly completed, and when so, only ½ or ¼cc. of the double normal solution of $MnSO_4$ should be added at a time, until the solution is perfectly colourless. The contents of the flask should then be diluted considerably, and the precipitate allowed to settle before filtration. Very little washing of the precipitate will thus be required.

It is well to subject the filtrate to direct titration, after acidifying with H_2SO_4, and raising nearly to boiling temperature. If the original body operated upon be not capable of direct titration, while the filtrate is, the formation of oxalic acid will be rendered probable. If, however, the filtrate be not capable of direct titration, then oxalic acid cannot be a product of oxidation. If both the original body and the filtrate be capable of direct titration, then the difference between the amounts of $KMnO_4$, reduced in the two cases, may prove a factor of importance.

Should the amount of $KMnO_4$ absorbed by the filtrate, and that reduced by the body in alkaline solution, not be equivalent to the whole of the oxygen demanded by the body for complete oxidation, then an oxidation in acid solution should follow the alkaline one. This is easily accomplished by adding the requisite amount of H_2SO_4 to neutralise the solution after oxidation in alkaline solution is complete. Then 20cc. $5nFePO_4$ are added, and the solution is heated for half-an-hour longer on the water-bath, and treated as described in Part I.

OXIDATION BY MNO_2 IN ALKALINE SOLUTION.

The MnO_2 is formed as already described in treating of oxidation by MnO_2 in acid solutions. It is necessary to filter the solution after it has become colourless, to get rid of the excess of $MnSO_4$. After washing the precipitate once, it is washed down into the flask in which it was formed, the filter, which will retain a small portion of the MnO_2, being carefully reserved until the end of the operation. 15cc. $5nNaHO$ are then added to the precipitate, together with 50cc. of the normal organic solution. The bulk is made up to 250cc., in a 500cc. flask, and the contents heated on the water-bath for half-an-hour, with agitation at intervals. The boiling is very irregular if placed directly over a Bunsen burner. I have ascertained that no loss of oxygen occurs here from the mere heating of the MnO_2 in the alkaline solution. After heating, the solution is considerably diluted and filtered, and the remaining MnO_2 determined in the manner already prescribed. It is evident that if considerable reduction take place an error would creep in, owing to the gain of oxygen by the manganous hydrate on the filter. Owing to this fact, and to the impracticability of obtaining a better circulation of the manganese dioxide in the solution, it is doubtful if more than approximate results will be obtained from this method. The filtrate could be directly titrated as in the method previously considered. If no oxidation occurred with $KMnO_4$ in alkaline solution, it would be quite unnecessary to subject the body to this treatment with MnO_2.

OXIDATION BY MNO_2 IN NEUTRAL SOLUTIONS.

If MnO_2 be formed in the manner already described, and washed until no free acid is present ; and oxalic acid, previously exactly neutralised, be heated with the precipitate on the water-bath, it will be found on filtration of the solution that the oxalic acid has been oxidised to some extent. That this is not due to a mere retention of the oxalate by the precipitate is proved by washing the latter with dilute alkali, which we have found to dissolve out the precipitated oxalate. It is evident, therefore, that on the addition of alkali to the precipitated MnO_2 a point would be reached at which no oxidation of the oxalic acid would occur. Now, this point I have found to correspond to the formation of the compound $K_2Mn_5O_{11}$, according to the equation—$2K_2C_2O_4 + 11MnO_2 = 2K_2Mn_5O_{11} + MnC_2O_4 + 2CO_2$. From this equation we see that, if MnO_2 and $K_2C_2O_4$ be added in the theoretical proportions for complete oxidation (in acid solution), $\frac{1}{11}$th of the oxalate would be oxidised before the complete formation of this compound. In experiments in which 50cc. *n*-oxalic acid exactly neutralised were added to the MnO_2 obtained from 50cc. $nKMnO_4$, only 44·7cc. of the oxalate were found in the filtrate, after thoroughly washing the precipitate with alkali, corresponding very nearly to the oxidation of $\frac{1}{11}$th of the total as shown above. We further learn from the above equation, that the quantity of alkali necessary to be added to the solution to render it neutral to oxalic acid, is exactly $\frac{1}{5}$th of that required to neutralise the whole of the oxalic acid which the amount of MnO_2 present is capable of exactly oxidising in its reduction to MnO. Now, as 1cc. *n*-oxalic acid (in reference to $KMnO_4$) requires 0·18cc. *n*-alkali to neutralise it, it is evident that the MnO_2 obtained from 1cc. $nKMnO_4$ requires one-fifth of this amount of alkali to render it neutral to the oxidation of the oxalate. It is advisable, however, to add a little more than is represented above, as less danger is likely to ensue by the solution being slightly alkaline than if it were slightly acid. The following experiments show that 0·05cc. $nNaHO$ added for every cc. $nKMnO_4$ precipitated is quite enough—*i.e.*, 50 per cent. in excess of the theoretical quantity required :—

No. of Experiment—	312	313	314
cc. *n*NaHO added	0	9	2·5
cc. *n*-oxalic acid deficient in filtrate	5·4	0·0	0·0
cc. $KMnO_4$ lost by precipitation	5·5	0·1	0·1

It will be unnecessary to describe this method further, as the other particulars with reference to it are common to the oxidation by MnO_2 in acid and alkaline solutions. It is preferable to obtain complete circulation of the MnO_2 by boiling the solution in a 500cc. flask, as was recommended in oxidising in acid solutions.

OXIDATION BY $KMnO_4$ IN NEUTRAL SOLUTIONS.

The *modus operandi* is exactly similar to that in alkaline solution, with, of course, the omission of the alkali. In order to preserve the solution neutral it is necessary to add alkali during precipitation by the $MnSO_4$ to neutralise the H_2SO_4 liberated. From the above remarks on oxidation by MnO_2, it will be evident that alkali should be added to satisfy the following equation:— $K_2Mn_2O_8 + 3MnSO_4 + 6NaHO = K_2Mn_5O_{11} + 3Na_2SO_4 + 3H_2O$. It is easy to calculate that 1cc. $nKMnO_4$ would require 0·212cc. $nNaHO$ to render it neutral after precipitation. It is here also advisable to add rather more than the theoretical quantity. I find a solution of NaHO ¼-normal is very convenient. Each cc. contains sufficient alkali (with 20 per cent. excess) to neutralise 1cc. of the double normal $MnSO_4$ solution, which I employ for precipitation. These solutions, being added in small and equal quantities at a time, the solution remains nearly neutral during the whole of the precipitation. The following experiments show the results obtained by this method, with 50cc. n-oxalic acid exactly neutralised:—

No. of Experiment.	cc. $nKMnO_4$ added.	Time of Heating.	cc. n-Alkali added before or during Precipitation.	cc. n Oxalic Acid deficient in Filtrate.	REMARKS.
315	50	1hr.	50KHO	1·7	Total gain of oxygen, 2·4cc.
316	50	1 „	100KHO	0·1	Total gain of oxygen, 1·2cc.
317	100	½ „	$12KHCO_3$	22·4	—
318	100	½ „	$12K_2CO_3$	10·3	—
319	100	½ „	12NaHO	0·1	Total gain of oxygen = 0·1cc.: 0·9cc. deficient in the first (neutral) filtrate.

We learn from 316 that the deficiency of oxalate in the filtrate in 315 is due, not to oxidation, but to mere precipitation, since it can be dissolved out by increasing the amount of alkali. A considerable gain of oxygen was recorded in these two experiments, owing to the $MnSO_4$ having been added in large (25 per cent.) excess. In the last three experiments, little more than the theoretical amount of alkali necessary to preserve the solution neutral was added. It is worthy of remark that the acid carbonate seems to be incapable of neutralising the H_2SO_4 liberated, while the normal carbonate is only capable of doing so partially. The caustic alkali, on the other hand, is perfectly efficacious. In Experiment 319 the actual conditions of working were fulfilled. After heating, the solution was precipitated with $MnSO_4$, with which the alkali was simultaneously added. The solution was then diluted, and after the precipitate had settled it was filtered. After washing slightly with distilled water, the precipitate was washed down into its own flask again; 150cc. nK_2CO_3 were added, and the solution heated on the water-bath, and again filtered. In the first filtrate there was a deficiency of 0·9cc. n-oxalic acid, but this was nearly completely restored after the treatment of the precipitate with the alkali.

In the table on following page, the various methods which I have discussed are conveniently arranged, and briefly described for reference. The composition of the different solutions employed is also given.

It is very probable that this table will require to be modified in some of its details; but the general principles underlying these methods have been so repeatedly confirmed, and the standard tests to which they have been submitted so satisfactorily complied with, that the general outline of the system will remain unaffected thereby.

ADDENDA TO OXIDATIONS BY $KMnO_4$ IN ACID SOLUTIONS.*

Modification in the case of Bodies not completely Oxidised.—I have found that some bodies are so difficult of oxidation when only the last traces remain, that a modification of this method is required. The simplest general method for determining whether the oxidation is complete will be to employ only one-half the prescribed quantity of the organic solution, and give the same length of heating. This will prove more expeditious than increasing the latter. In acid solutions, if a considerable reduction of the organic body takes place with the prescribed quantities (say more than 60 per cent. of the total possible), I prefer to perform another experiment, using 75cc. instead of 50cc. $2nKMnO_4$, preserving the other proportions. There is necessarily a slight increase in the error. This error amounts to not more than 0·18cc. $nKMnO_4$ per half-hour, or 0·35 per cent. of the body operated upon. This result was obtained from an experiment (No. 320) with 75cc. $2nKMnO_4$ and 50cc. n-oxalic acid. After heating for two and a-half hours on the water-bath, a loss of oxygen = 0·9cc. $nKMnO_4$ was recorded.

On the Influence of Chlorides.—A condition which has long been insisted upon, in titrations with potassium permanganate, is that chlorides, and especially free HCl, should be absent. Now Lunge† and others have shown that titrations with $KMnO_4$ may frequently be effected in the presence of large quantities of chlorides, without any error arising. Of course any error which would arise in direct titrations would be considerably increased by the high temperature and the large excess of $KMnO_4$ which I employ. The experiments in the first table on page 270, however, show that the errors introduced by the presence of small quantities of chlorides is very small indeed with the conditions of working which I have described. In each case the error due to the loss of oxygen in absence of the chloride has been deducted, and the normal conditions obtained, unless where otherwise stated.

We see that with such quantities of chlorides as are equivalent to 0·3 or 0·5 NaCl the loss with half-an-hour's heating is very slight indeed, more especially if an organic body is present. From Experiment 323 it will be seen that the error with the usual length of heating would be only 0·1 per cent. in the case of an organic body capable of complete oxidation. Although the evolution of chlorine is somewhat less when the $FePO_4$ is present than when it is replaced by even a smaller amount of H_2SO_4 than it contains (325), it has not the same influence here as it has in preventing the loss of oxygen from the mutual action of MnO_2 and $KMnO_4$. In the alkaline solution (327), as we had expected, there is no liberation of chlorine or loss of oxygen. It should be particularly noted, in Experiment 328, that although NaCl was added equivalent to more than the whole of the free acid in the $FePO_4$ solution, a

---

* As several experiments with cane sugar are quoted in the first part of this paper, I should state that I have since found the sample employed to be very *impure*. With pure crystallised cane sugar, I obtain *complete* oxidation to CO_2 and H_2O. Glycerin and tannin may also be completely oxidised by adopting the modification here recommended.

SCHEME OF ORGANIC ANALYSIS.

OXIDATION IN ACID SOLUTION BY:—

KMnO_4. (I.)

50cc. $2n\mathrm{KMnO}_4$ + 20cc. $5n\mathrm{FePO}_4$ + 50cc. n-organic solution, made up to neck of a 250cc. flask, with distilled water. Heat 35 minutes on water-bath. Pour contents *gently* into an 800cc. beaker, containing sufficient (say 25cc.) excess $n\mathrm{FeSO}_4$. Rinse flask with solution, if necessary. Make up bulk to 700 or 750cc., with *cold* distilled water, and titrate back at once with $2n\mathrm{KMnO}_4$. Let a = number of cc. $2n\mathrm{KMnO}_4$ equivalent to FeSO_4 added, and b = number of cc. $2n\mathrm{KMnO}_4$ absorbed in titration. Then for a body considerably oxidised :—

% total oxidation $= 4(50 + b - a - 0{\cdot}05)$.

For a check experiment, employing 75cc. $2n\mathrm{KMnO}_4$:—

% total oxidation $= 4(75 + b - a - 0{\cdot}1)$.

MnO_2. (II.)

In a 500cc. boiling flask mix—50cc. $2n\mathrm{KMnO}_4$ + 55cc. $2n\mathrm{MnSO}_4$. Heat on water-bath two minutes. When colourless, filter. Discard filtrate. Wash precipitate down into its original flask. Preserve filter. Add 10cc. $5n\mathrm{H}_2\mathrm{SO}_4$ + 50cc. n-organic solution, and make up bulk to about 250cc. Boil half-an-hour, first gently, finally briskly. Dilute considerably, and filter.

Precipitate.	Filtrate and Washings.
Wash twice with warm water. Wash down into original flask. Dissolve, together with any MnO_2 adhering to this or to the reserved filter, in excess $n\mathrm{FeSO}_4$, and titrate back with $2n\mathrm{KMnO}_4$.	Add 10cc. $5n\mathrm{NaHO}$ + 20cc. $5n\mathrm{FePO}_4$ + 75cc. $2n\mathrm{KMnO}_4$, and make up to neck of a 750cc. flask. Heat one hour, and proceed as directed in (I.). % total oxidation $= 4(75 + b - a - 0{\cdot}1)$.

For a check experiment, employ only 25cc. n-organic solution

OXIDATION IN ALKALINE SOLUTION BY:—

KMnO_4. (III.)

In a 750cc. flask mix 50cc. $2n\mathrm{KMnO}_4$ + 15cc. $5n\mathrm{NaHO}$ + 50cc. n-organic solution (neutralised), and make up bulk to 250cc. Heat 35 minutes on water-bath. Should considerable reduction occur, after a quarter of an hour's heating, add extra 25cc. $2n\mathrm{KMnO}_4$. Add 75cc. $n\mathrm{NaHCO}_3$, and subsequently $2n\mathrm{MnSO}_4$ (*slowly*, with constant agitation), until solution is *just* rendered colourless. Dilute considerably with hot distilled water, allow precipitate to settle, and filter through paper previously washed with boiling dilute NaHO.

Precipitate.	Filtrate and Washings.
Wash twice with hot water as rapidly as possible. Wash down into original flask. Dissolve in excess $n\mathrm{FeSO}_4$, and titrate back with $2n\mathrm{KMnO}_4$.	Heat to boiling temperature. Add 10cc. $5n\mathrm{H}_2\mathrm{SO}_4$, and titrate directly with $2n\mathrm{KMnO}_4$.

For a check experiment employ only 25cc. n-organic solution.

MnO_2. (IV.)

The MnO_2 is obtained as directed in (II.). After washing the precipitate once on the filter with warm water, it is washed down into its original flask, and 15cc. $5n\mathrm{NaHO}$ + 50cc. n-organic solution added, the bulk being made up to 250cc. Heat 35 minutes on water-bath, with frequent agitation, dilute considerably, and filter through paper previously washed with boiling dilute NaHO.

Precipitate.	Filtrate and Washings.
Wash twice with hot water as quickly as possible. Wash down into original flask. Dissolve, together with any MnO_2 adhering to this or to the reserved filter, in excess $n\mathrm{FeSO}_4$, and titrate back with $2n\mathrm{KMnO}_4$.	Heat to boiling temperature. Add 25cc. $5n\mathrm{H}_2\mathrm{SO}_4$, and titrate directly with $2n\mathrm{KMnO}_4$.

For a check experiment employ only 25cc. n-organic solution.

OXIDATION IN NEUTRAL SOLUTION BY:—

KMnO_4. (V.)

In a 750cc. flask mix 50cc. $2n\mathrm{KMnO}_4$ + 50cc. n-organic solution (exactly neutralised) + 150cc. distilled water. Heat 35 minutes on water-bath. Add $2n\mathrm{MnSO}_4$ *slowly*, and with constant agitation, until the solution is *just* rendered colourless, each addition being *preceded* with an *equal volume* of $\frac{1}{4}n\mathrm{NaHO}$. Dilute considerably with warm water; allow the precipitate to settle, and decant the solution through a paper filter previously washed with boiling dilute NaHO. To the precipitate add 10cc. $2n\mathrm{Na}_2\mathrm{CO}_3$ and dilute considerably with boiling water. Heat on water-bath for a few minutes with agitation. Filter, and proceed as directed in (III.).

MnO_2. (VI.)

The MnO_2 is obtained as directed in (II.). After washing the precipitate twice on the filter with warm water, it is washed down into its original flask, and 20cc $\frac{1}{4}n\mathrm{NaHO}$ + 50cc. n-organic solution added; the bulk being made up to 250cc. Boil for half-an-hour, at first gently, and finally briskly. Proceed further as directed in (IV.).

For check experiments in this and (V.) employ only 25cc. n-organic solution.

much less loss of chlorine is the result than when the same equivalent of free HCl is added *instead of* the $FePO_4$ solution (329). This pointed to the possibility of checking the action of even a large quantity of free HCl by fixing it with the addition of a neutral salt. In Experiment 330 this has been successfully accomplished by means of Na_2SO_4, the loss being very slight indeed, considering the large amount of free HCl added. Experiments 331 and 332 yield further confirmation that the amount of chlorine evolved depends upon the amount of *free* HCl, not *added*, but present after the solution has *assumed stability*, as well as upon the *total* free acid present.

No. of Experiment.	Grms. NaCl added.	Time of Heating.	Loss—c.c. $nKMnO_4$.	REMARKS.
321	0·325	½hr.	0·2	
322	,,	10mins.	0·7	$FePO_4$ solution replaced by 50cc. n H_2SO_4.
323	,,	2hrs.	0·2	50cc. n-oxalic acid added.
324	1·0	,,	1·5	
325	0·5	2½hrs.	1·6	$FePO_4$ solution replaced by 50cc. n H_2SO_4.
326	0·5	,,	1·2	
327	0·5	½hr.	0	Experiment in alkaline solution.
328	5·0	,,	6·0	
329	75cc. nHCl	,,	53·4	The HCl replaced the $FePO_4$ solution.
330	50cc. nHCl	,,	0·6	HCl replaced $FePO_4$ solution. 100cc. n Na_2SO_4 added.
330*a*	75cc. nHCl	,,	0·6	As above, but 200 Na_2SO_4 added.
331	37½cc. nHCl	,,	7·7	HCl replaced the $FePO_4$ solution.
332	,,	,,	14·9	37½cc. nH_2SO_4 added in addition, but no $FePO_4$ solution.

Now, it seems to me that we must look for the explanation of these results in the thermo-chemical investigations of Thomsen. The following experiments were instituted to decide this point. In the first table no base, except that of the $KMnO_4$ added, was present, and HCl and H_2SO_4 were employed in varying proportions to produce a total of 75cc. n-acid. Of course no $FePO_4$ solution was introduced :—

No. of Expt.—	333	334	335	336	337	338	339	340
cc. nHCl added	15	35	40	45	50	55	60	75
Length of heating	¾hr.	¾hr.	¾hr.	¾hr.	¾hr.	¾hr.	¾hr.	¾hr.
Loss = c c. $nKMnO_4$ ..	4·6	13·4	18·4	11·4	11·8	11·0	15·4	40·8

As an average result of the above experiments, we may state that 1cc. nHCl in the free state is equivalent to a loss of 0·9cc. $nKMnO_4$ per hour. In the next series of experiments, 75cc. nH_2SO_4 were added instead of the $FePO_4$ solution, and varying amounts of NaCl. The time of heating was half-an-hour in each case.

No. of Experiment—	341	342	343	344
cc. nNaCl added	15	35	55	75
Loss = cc. $nKMnO_4$ ..	2·1	9·2	12·4	21·6
Equivalent to a loss arising from—cc. n *free* HCl	4	20	27	47

It would seem from the above that the amount of HCl which the H_2SO_4 is capable of liberating increases in a greater ratio than the amount of NaCl present. It should be borne in mind, however, that the evolution of oxygen would have increased faster, also, if no chloride had been present, owing to the absence of $FePO_4$.

I was anxious to find if the amount of free HCl present (with a constant amount of total free acid and a known amount of base), as indicated by the quantity of Cl evolved, would correspond to the avidity of HCl as given in Thomsen's table. The following experiments were therefore instituted :—100cc. nHCl were added in each case (except No. 346), and 100cc. of the given neutral and normal salts employed. In order to render the error due to the small amount of K_2O in the permanganate smaller, only 50cc. $nKMnO_4$ were employed. The heating lasted in each case a quarter of an hour.

No. of Experiment.	Salt added.	cc. $nKMnO_4$ lost.	REMARKS.
345	none	9·8	
346	none	5·4	50cc. HCl replaced by 50cc. nH_2SO_4
347	Na_2SO_4	6·4	= about 70 free HCl.
348	$NaNO_3$	20·8	Another gave = 20·6.
349	CH_3COONa	3·8	Another gave 3·4 = about 40cc. n free HCl.
350	Na_2HPO_4 + 33·3cc. nNaHO.	0	

The relative "avidities" of the different acids for sodium, calculated from the above results, are, roughly :—$HCl = 100$, $H_2SO_4 = 175$, $CH_3COOH = 50$, and $H_3PO_4 = 0$. These numbers do not agree with those given by Thomsen, and this may be owing to the high temperature at which the experiments were made.* It is a very general result, however, of all these experiments that in boiling dilute solutions H_2SO_4 has a much greater avidity for Na_2O than HCl. The influence of HCl and HNO_3 united is very marked (348). The loss is much greater than with HCl alone, although HNO_3 itself causes no loss, as we shall presently see. The cause is no doubt due to the formation of aqua regia, which assists the oxidation of the HCl.

The practical outcome of these experiments is that the loss of oxygen due to the presence of even

---

* In the March number of the *Berichte* (xx. p. 556) I note that G. A. Hagemann criticises very severely the groundwork of Thomsen's "avidity" calculations. If Hagemann's position be accepted, then the influence of the Na_2SO_4 must be ascribed to the alkaline nature of the residual energy ("Restenergie") of the sulphate in solution. I find that the addition of Na_2SO_4 in *very large quantity* diminishes the loss of oxygen which occurs in acid solution when no $FePO_4$ is present.

large quantities of free HCl may be avoided by the addition of sufficient Na_2SO_4 to fix practically the whole of the HCl.[*]

On the Influence of Nitric Acid and Ammonium Salts.—That these are without influence is shown by the following experiments, in which the usual conditions prevailed :—

No. of Experiment.	Addition.	Length of heating.	cc. $nKMnO_4$ lost.	Remarks.
351	0·5grm. KNO_3	2½hrs.	0	
352	„	„	0	$FePO_4$ replaced by 50cc. nH_2SO_4
353	0·5grm. KNO_3 + ·5grm. NaCl	„	0·6	No greater loss by addition of KNO_3
351	0·5grm. NaCl	„	0·6	
355	8grms. KNO_3	½hr.	0·2	Loss due to impurity.
356	„	2½hrs.	0·2	
357	75cc. $nHNO_3$	½hr.	0·9	HNO_3 replaced the $FePO_4$
358	„	2½hrs.	1·0	Loss due to impurity.
359	100cc. $n(NH_4)_2SO_4$	½hr.	0	
360	„	½hr.	0·15	$FePO_4$ replaced by 75cc. nH_2SO_4

We learn from these experiments that HNO_3 might even be employed as a substitute for H_2SO_4, if the impurity which it contained were allowed for. There is practically no greater loss in Experiment 358, after 2½ hours' heating, than in the previous experiment, with only half-an-hour's heating.

It is very evident that in the analysis of potable waters, no error would be introduced by adopting this method, owing to the presence of chlorides, nitrates, and ammonium salts. Nitrous acid would, of course, be oxidised to nitric acid.

Ultimate Analysis by means of $KMnO_4$.—I have obtained further encouraging results, which lead me to expect that my method will prove well adapted to the above purpose. I am designing a modification of Lunge's nitrometer for the purpose of collecting and measuring the gases evolved, and I hope soon to communicate the results I obtain therewith to the Society.

I might state here also that I find that some bodies which are not at all attacked by $KMnO_4$, even in acid solutions, may be completely oxidised by the introduction of a *carrier* of oxygen in very small quantity. By this means the number of organic bodies withstanding the action of $KMnO_4$ will be considerably diminished, if not even reduced to nil.

The Sixth Meeting of the Fourth Session of this Section was held in the Rooms, 207, Bath Street, Glasgow, on Tuesday, April 5, 1887.

MR. J. NEILSON CUTHBERTSON IN THE CHAIR.

DISCUSSION ON MR. SUTHERLAND'S PAPER ON SCALE TESTING (THIS JOURNAL, VI. 123).

THE SECRETARY read the following letter from Mr. BOVERTON REDWOOD :—

85, GRACECHURCH STREET, LONDON,
March 30, 1887.

D. A. SUTHERLAND, Esq.,
BURNTISLAND OIL WORKS,
BURNTISLAND.

DEAR SIR,—I regret that I shall be unable to be present when your interesting and valuable paper on paraffin scale testing is discussed.

With reference to the differences between the method of determining oil proposed by the Scottish Mineral Oil Association, and that which I adopt, I should like to make the following remarks.

1. The press, of which Mr. McCutchon was good enough to send me drawings, appears well designed, and would, I have no doubt, furnish results quite as satisfactory as those which I obtain with my press, provided that the spiral springs remain of unimpaired elasticity.

2. My experiments indicate that the application of a higher pressure than that which I employ is not necessary to the attainment of strictly comparative results, and may in some cases cause loss of the solid material.

3. The principal objection to a lengthened duration of pressure is that the difficulty of maintaining the standard temperature throughout the test is increased.

4. I prefer to work with 500grs. rather than with 250grs., because the loss of solid material, by adherence to the press cloths, etc., bears a smaller ratio to the total in the former case than in the latter.

Against the objections specified, I am not aware that there are any marked advantages to be set, having regard to the fact that the test must always remain a purely arbitrary one.—Yours truly,

BOVERTON REDWOOD.

Mr. IVISON MACADAM, in a communication made to the Secretary, desired to bear testimony to the great advisability of securing some definite and fixed process for the testing of scales. About two years ago he had occasion to show that the usual volumetric process was inaccurate, and gave results decidedly too high, being thus unfair to the manufacturer. For some years he had adopted the process described by Mr. Sutherland as in use in Dr. Wallace's laboratory, and found it to give constant and fair results.

Mr. R. TERVET said that he was sure the Section was very much indebted to Mr. Sutherland for bringing before the Society such a complete synopsis of the

---

[*] Since writing the above, I have found that the presence of chlorides, even in very small quantities, produces marked irregularities in the oxidation of nitrogenous bodies (including ammonium salts) by $KMnO_4$. To obviate these irregularities the addition of the sodium salt is absolutely necessary, and I would recommend 50 parts of crystallised sodium sulphate to be added for every part by weight of chlorine which the amount of solution employed contains. I have also a modification of this method in view, for the determination of the *nitrogenous* organic matter in waters, in addition to the other organic constituents which will be estimated by the process as already described.

various methods in use for the analysis of crude paraffin scale, as pursued in our works laboratories, and also in those outside where such testings are done. From a practical point of view, however, he did not think any of the processes mentioned are likely to get us out of the difficulties which beset the question. It is well known that when we have to valuate a crude mineral oil, we submit it to a course of purification and analysis identical with that pursued on the practical scale in our works. The results are expressed in terms of per cent. of burning oil, intermediate oil, lubricating oil, naming the specific gravity of each, and per cent. of scale, with its melting point. From these figures the value of the crude oil is determined. With regard to scale, the matter is quite different. It is manufactured and delivered in a state of purity—that is, the substances associated with it are not chemically combined with the scale. The analysis ought, therefore, to be very simple, but we find both in theory and practice the contrary to be the case. Mr Boverton Redwood on this subject touches the keynote when he says (this Journal, iii. 432): "To the fact that the test must under any circumstances be only an arbitrary one, the value to the buyer lies in its association by experience with results obtained in practical working the material." This is exactly the base upon which many of our commercial analyses stand—viz.: An arbitrary test which cannot be dissociated from results obtained in practical working. The mineral oil refiner buys his crude oil by an arbitrary test, the results of which tell him what he may expect from the practical working. It seems curious indeed, then, that the practically exact method of valuating nearly every substance that is bought and sold by analysis should not be extended to paraffin scale. It would appear from what has been said and written on the subject, and also from the minutes of the Scottish Mineral Oil Association, that the difficulty is in the estimation of the oil. Now, if it is an arbitrary test, independent of what results may be obtained in practical working, that is wanted, or in other words, if the test is simply to ascertain what proportion can be expressed from a sample of scale under given conditions, then the method employed by Mr. Boverton Redwood furnishes all that is required. But it must be urged that it is a mistake to adopt a method of analysis for a substance which is to undergo manufacture, which has no bearing for, and gives no indication of, what result may be expected in practice. As an example; if the time—viz.: 15 minutes, prescribed by the Scottish Mineral Oil Association had been adopted to press the samples A, B and C, as shown in Mr. Boverton Redwood's paper, they would have contained after pressing respectively, 1·24: ·85: ·70 per cent. of oil which their test took no cognisance of. This is clearly shown by the fact that when the times of experiment were extended to sixty minutes the results obtained were practically constant, and no further absorption took place by extending the time to 120 minutes. To make this clear he took the liberty of quoting a few of Mr. Boverton Redwood's numbers. (See table on preceding column.)

Reference Number.	Mark of Sample.	Quantity in Grains.	Pressure in Tons.	Tempt. in degrees F.	Time in Minutes.	Percentage of Oil.
1	A	500	9	60	5	5·30
2	,,	,,	,,	,,	15	7·52
3	,,	,,	,,	,,	30	7·92
13	,,	250	,,	,,	5	6·40
14	,,	,,	,,	,,	15	8·16
15	,,	,,	,,	,,	30	8·60
25	B	500	,,	,,	5	11·04
26	,,	,,	,,	,,	15	12·22
27	,,	,,	,,	,,	30	13·08
37	,,	250	,,	,,	5	11·68
38	,,	,,	,,	,,	15	12·88
39	,,	,,	,,	,,	30	13·21
49	C	500	,,	,,	5	6·12
50	,,	,,	,,	,,	15	7·81
51	,,	,,	,,	,,	30	8·54
60	,,	250	,,	,,	5	6·84
61	,,	,,	,,	,,	15	8·44
62	,,	,,	,,	,,	30	8·80
4	A	500	,,	,,	60	8·62
5	,,	,,	,,	,,	120	8·58
16	,,	250	,,	,,	60	9·08
17	,,	,,	,,	,,	120	9·01
28	B	500	,,	,,	60	12·98
29	,,	,,	,,	,,	120	13·22
40	,,	250	,,	,,	60	13·20
41	,,	,,	,,	,,	120	13·60

From these figures we see that at a temperature of 60°, and at a pressure of 9 tons, which may vary from 5 to 60 minutes in duration, the results obtained differ:

For A .... 5·30 to 9·08 = 3·78%
,, B .... 11·04 to 13·20 = 2·16
,, C .... 6·12 to 8·81 = 2·72

It may be said that the comparison is not fairly made, as the times and quantities vary, and that the two extremes in time are taken—viz., 5 to 60 minutes, but an inspection of Mr. Boverton Redwood's figures, as tabulated above, will show that his results are remarkably concordant throughout the whole series for any particular time. Therefore, if this was the only difficulty all that need be decided is what quantity should be taken for the test, and what time should be employed in testing.

From what has been said, one need feel no surprise that Mr. Sutherland should meet with differences of 2 per cent. in the results obtained by two different analysts. Such differences are almost certain to continue, until it forms part of the analytical process, that the pressing of the sample shall be continued until its weight remains constant.

Perhaps the most interesting and valuable results obtained by Mr. Boverton Redwood are those done at a temperature of 70° F. It is to be regretted, however, that particulars are wanting with regard to melting points, before and after pressing; also the "setting" point of that portion which is expressed.

In tabulating the experiments made at 70° F., no notice was taken of results obtained by pressing for 5 minutes, for reasons already stated. (See table on p. 273.)

When we compare the figures thus obtained between 15 and 30 minutes' pressure, the results are remarkably constant, the greatest variation being in sample A. Again, when those tests done at 30 minutes for both quantities, and of the three samples, we have a set of results which leave little to be desired, the greatest difference being 0·3, and the least 0·1. As hot-pressing is an approach to the practical method of refining paraffin scale, he was of opinion that one hour should be given, even at a temperature of 70° F.

Mr. Sutherland says, page 124, vol. vi., "Scale is of value to the candlemaker and refiner, only for the wax it contains, of a melting point higher than that of the ordinary temperature, consequently he makes a claim upon each delivery . . . for what he terms oil, which, however, consists mostly of soft paraffin held in solution." Mr. Boverton Redwood says: "From an examination of the foregoing figures, it will be seen that the results are most influenced by variations of temperature. . ." Moreover, I am of opinion that in some cases, at any rate, a portion of the semi-solid hydrocarbons contained in the scale, which certainly cannot fairly be called oil, is gradually squeezed out during a prolonged pressure of so thin a cake.

Reference No.	Mark of Sample.	Quantity taken in grains.	Pressure in tons.	Temperature in degrees F.	Time in minutes.	Percentage of Oil.
10	A	500	9	70	15	11·62
11	,,	,,	,,	,,	30	12·26
22	,,	250	,,	,,	15	12·00
23	,,	,,	,,	,,	30	12·56
31	B	500	,,	,,	15	11·72
35	,,	,,	,,	,,	30	15·20
46	,,	250	,,	,,	15	15·08
47	,,	,,	,,	,,	30	15·32
56	C	500	,,	,,	15	10·22
57	C	,,	,,	,,	30	10·66
67	,,	250	,,	,,	15	10·61
68	,,	,,	,,	,,	30	10·76

He thought these statements brought the matter to an issue, and indicated exactly upon what line the examination of a paraffin scale should be conducted. Now, as scale is of value to the candlemaker only for the wax it contains, which is capable of being made into candles; and as it is not the business of the wax refiner or candlemaker to extract soft paraffin held in solution, it is only reasonable that he must, and should, reject that portion he cannot use. This finds ample confirmation from the case cited by Mr. Sutherland, when he says, page 123: "Somewhat recently I have had occasion to test a large number of samples. . . . That my results were accurate according to the method I used, was proved, ere repeated arbitration, by the public analyst whose method it was. *But the buyers were still unsatisfied, and adhered to their own results.*" Now, if it is safe for us to assume that the scale referred to was made in cold weather, then we may possibly find the reason why the buyers adhered to their own results, from Mr. Sutherland's own explanations. As he says, further on, "The claim is generally allowed up to 6 per cent., being less in summer, or when the weather is warm, and *greater in winter time and cold weather, when the cooling power is greater, and a corresponding increase of soft paraffin extracted.*"

Further, those paraffins whose melting point is *immediately* above the ordinary temperature, and the semi-solid hydrocarbons contained in the scale which cannot be called oil, are of little or no use to the candlemaker, and are an unfailing nuisance to the wax refiner, entailing much loss and endless labour.

In order to see what relation the low melting points of paraffin scale and wax have to ordinary temperatures, he would refer to his "Note on an Improved Apparatus for the Manufacture of Refined Paraffin Wax" (to follow next month).

He did not mean to say that the melting points there shown are the lowest obtainable, because they are derived from a fractional distillation, and are therefore controlled by Kopp's law for mixed boiling points, and it is certain that lower fractions and a different curve would be obtained by fractional fusion.

It is quite obvious, then, that the only way of properly testing paraffin scale is to convert it into a substance of a composition similar to that from which candles are made, or for whatever purpose the wax is to be used; perhaps the most simple and direct method is exactly that adopted by Mr. Boverton Redwood—viz., hot pressing at a temperature suitable for each grade of scale. Mr. Boverton Redwood's figures are important in another direction, inasmuch as they show how the results may be interpreted, and what influence they have on buyer and seller. Suppose we allow—

8 % as deduction for oil in sample A
12 ,, ,, B
8 ,, ,, C

and after deduction the value of the scale is 2d. per unit—

A 100 − 8 = 92 × 2d. = 184d.
B 100 − 12 = 88 × 2d. = 176d.
C 100 − 8 = 92 × 2d. = 184d.

But to the candle-maker, after the soft and worthless paraffin had been removed, at a temperature even as low as 70° F., they would stand relatively thus:—

A − 12 = 88 × 2d. = 176d.
B − 15 = 85 × 2d. = 170d.
C − 10 = 90 × 2d. = 180d.

which gives a difference per 100 units for—

A − 7·36d.
B − 5·28d.
C − 3·68d.

Another very important point for the scale manufacturer is, that he is really selling to the wax refiner a product for which he is not receiving the full value. In the absence of exact figures in Mr. Boverton Redwood's tests I am only able to assume values which would be only approximately correct if we allow that the original scale had a melting point of 120° F., and the portion expressed a setting point of 85° F. Then:

	A.	B.	C.
Hot pressed scale....	125°, 88% ..	126°, 85% ..	124°, 90%
Oil and soft ,, ...	85 12 ..	85 15 ..	85 10

To summarise these remarks, he had only to repeat, first, that the only method for the analysis of paraffin scale which appeared to him likely to give satisfactory results must be constructed on the principle of that pursued in the manufacture of the refined substance, so that the results obtained may be a guide in the practical working of the material. This may be easily effected either by hot pressing or by "sweating." In the latter case it would only be necessary to submit a cake of the melted scale of a given thickness to a given temperature until it ceased to lose weight, or for a given time. An examination can then be made of the resulting wax, and also of the liquid portion which has been fused out of it.

In dealing with this latter portion a diagram is appended which may be found useful in ascertaining what percentage of solid paraffin these oily residues contain. It is not as perfect as could be wished, and, he might mention, it was constructed and drawn for this purpose by two workmen who attended his works' chemistry-class. Secondly, those very soft fractions of paraffin are almost valueless for candle making, and are in large part almost liquid at ordinary temperatures when isolated from the members of higher melting point. Hence the wax refiner designates them as oil. Besides, their presence degrades the melting point to an enormous degree of what would otherwise be a first-rate scale. This occasions serious loss to the scale manufacturer, and a corresponding gain to the refiner. Thirdly, those scales of irregular make, and which are described by Mr. Boverton Redwood as being "doughy"—that is, when the crystals are imperfectly formed by their interlocking a large proportion of oil which cannot be removed by cold pressing—would, by the test indicated, yield a result equal to, and parallel with, those obtained from scales of normal condition.

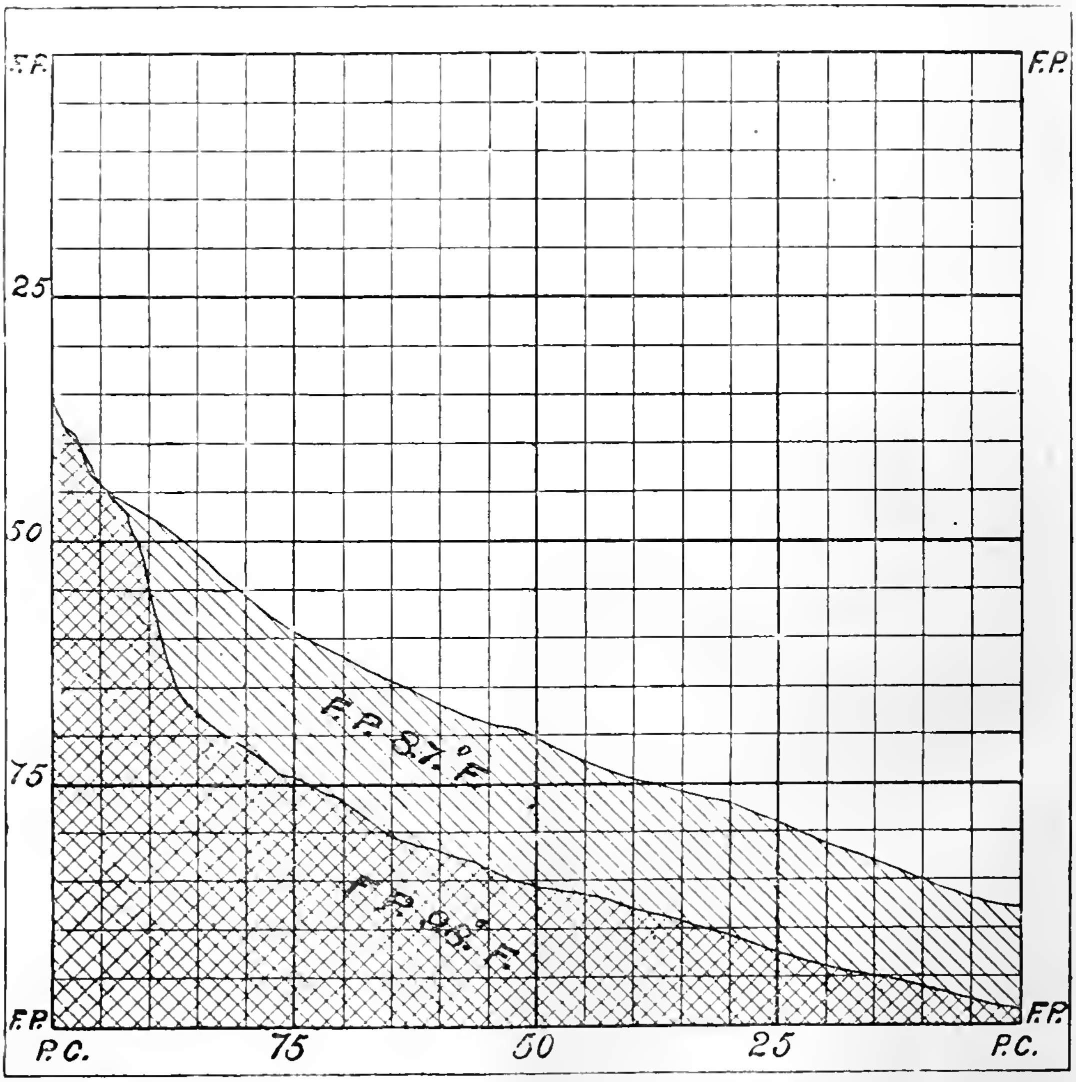

Diagram showing Per Cent. of Scale in Blue Oil and Corresponding Freezing Points.

Dr. Wallace said the previous speaker (Mr. Tervet) had given a very valuable contribution to the chemistry of scale testing. It was scarcely, however, a criticism on Mr. Sutherland's paper, but an entirely new idea—viz., that everything should be removed from the paraffin scale that was not required in the manufacture of candles. As far as he (the speaker) was concerned, he should be quite willing to test scale by any method which the manufacturer, on one hand, and the merchant on the other, had agreed upon: but, as was pointed out by Mr. Tervet, Mr. Sutherland and Mr. Redwood, this was not a strictly chemical test, or in any way like an analysis of potash salt or an iron ore, where the ingredients could be tested with perfect accuracy. It rather resolved itself into a question of the process adopted. The water and what was called the "dirt," or insoluble matter, could be determined quite accurately; but the estimation of the oil was a different matter, depending, as it did, on the process adopted and how much could be got out. For his own part, he had pursued for a number of years a course to which he had adhered and which he would have some difficulty in altering on account of the contracts running on between buyer and seller, and that was one reason why it was rather difficult to change processes. The press which he used was 5⅜in. in diameter, with a screw of 2in. in diameter and six threads to the inch. The cross-head, or lever, was 4ft. long, and was worked by an able-bodied man on each side. It might be pertinently asked, "How are you able to get men of equal strength every time you want them, and if you cannot get able-bodied men, how many others do you employ?" He had fixed upon a certain point with two strong men by having the screw of the press marked, and by this means the same amount of pressure was always approximately obtained. Taking 250 grains of the scale with the usual linen cloths, this was pressed for two minutes with five papers on each side, and afterwards for two minutes with two papers on each side, and an estimate was afterwards made of the water in the cake which was left. This was found to be quite sufficient, and the results were very consistent. He was quite aware, however, that when the temperature was advanced two or three degrees higher, or even one degree above 60, results were obtained considerably different. There seemed to be a general understanding between merchants and manufacturers of scale that a method such as this would be adopted when they sent samples of scale for analysis, and until these gentlemen could agree amongst themselves he feared that he would require to pursue the course he was doing, notwithstanding the improvements suggested by Mr. Sutherland and others.

Mr. Hamilton was afraid that Mr. Sutherland's ideas came rather late in the day. Six or eight months ago they might have been useful, but as affecting the analysis of Scotch oil companies there was, so far as he knew, only one small company producing scale for marketable purposes, and while the analysis of scale might be useful in the works as guiding the manufacturer of wax, still he did not believe that, as a commercial analysis, it was of any value now.

Mr. A. J. Liversedge brought before the Section several small tubes which he had used in connection with a small centrifugal testing machine in the testing of milk and other substances. This apparatus, which simply increased the action of gravity many times, had been found to answer the purpose for which it was originally introduced extremely well, and had given results sufficiently accurate for commercial purposes. It was suggested to him at the time Mr. Sutherland's paper appeared in the public press that this apparatus might be used for the purpose of facilitating the testing of paraffin scale, and with this object in view he procured some scale and made a series of experiments which seemed to be very successful so far as the test for water was concerned. The centrifugal action to which the melted scale was subjected in the machine did, as far as he could judge, render the separation of the water, dirt, and tarry matters both much more rapid and complete than separation by gravity unaided could accomplish in a reasonable time. One of the tubes submitted contained a crude scale showing the separation of water, etc., effected. He subsequently went further, to ascertain whether the apparatus could not be used for the purpose of separating the soft paraffin or oil. His idea was that it might be separated whilst in solution at a certain temperature and with a certain number of revolutions of the machine. He could not say that his success in that direction was very great—the separation of the so-called oil was obviously the most difficult part of the whole business. It appeared to him, however, that instead of endeavouring to ascertain the amount of water and dirt, and the amount of soft paraffin in a given sample of scale, the manufacturing process suggested by Mr. Tervet should be pursued—that is, find in any sample of scale the quantity of wax of the condition required by candle manufacturers. He had tried to see if the crude paraffin in a small quantity could not be rapidly refined, using the centrifugal machine to aid the operation, and the results thus ascertained in the course of a short time, instead of by the tedious process now adopted. He saw that a method of refining scale by macerating it with soapy water had been proposed, and as a matter of curiosity had made some experiments in this direction, and found that the scale was very much improved by the maceration in the water; but to what extent the soft paraffins were separated he had not been able to ascertain. He merely brought this centrifugal idea before the Section in a general way. It might suggest a new line of experiment, and if any members are disposed to pursue the question further in this direction he should be glad to lend him his assistance.

Mr. King, as a buyer of paraffin scale, considered that the main question was to arrive at a method of testing paraffin scale for oil, dirt, and water, which would please both buyer and seller. He was very dissatisfied, ever since scale was made, at the manner in which it was tested. He had to acknowledge that to Mr. Sutherland he was indebted for being amongst the earliest to adopt what might be called a sensible commercial test for paraffin scale. It had been said that the greatest difficulty was with the oil—*i.e.*, finding how much oil was in the scale. In his opinion the greatest difficulty lay in the discovery of the proper amount of water and dirt in the paraffin scale. The lever press employed by him was the same as used by Dr. Wallace, and if the screw was kept clean and well oiled the results would be, as in his case, invariably uniform. The *modus operandi* which he proposed should be as follows:—

For Oil.

1. Take 500 grains paraffin scale, free from dirt and water, crystallised by slow cooling, starting at 212° F., and coming down to 60° F.; the time occupied in the cooling process not to be less than 6 hours.

2. See that press is in good working order, screw clean, and well lubricated with good oil.

3. Temperature of press and atmosphere to be 60° F.

4. Place paraffin in press between single ply of finest linen, and 5 ply each side of white blotting paper (38lb. to the ream).

5. Screw up the press as fast as paraffin will allow without squeezing it out from between the discs.

6. Six minutes to be allowed from beginning to end of pressure, including the screwing down.

For Dirt and Water.

1. Weigh 1000 grains of paraffin scale and place it in a graduated glass tube, each division of same to indicate 10 per cent. of the whole.

2. Place tube containing paraffin in water, raised to and maintained at 190° F. until the dirt and water is perfectly settled to the bottom.

3. Pour off paraffin to within ¾in. to 1in. of the sediment at bottom of tube, refill with shale spirit, previously well washed in water, and let settle until dirt and water is again at bottom.

4. Pour off a second time, and refill again with shale spirit, mixing well and settling as before—read at bottom percentage of dirt and water.

5. The temperature of water in which the tube is immersed may be lowered when the shale spirit is introduced, and the reading taken at 60° F.

Mr. Sutherland, in replying, considered that it would be admitted that a subject which had elucidated perhaps, he might say, the longest discussion before this Section, could hardly yet have lost its importance to the chemical world, as Mr. Hunter and Mr. Hamilton would lead them to believe. Till candlemakers ceased using scale, and while scale, American or otherwise, was in the market, so long would it be necessary to test scale. He had to express his thanks to Mr. Boverton Redwood, Dr. Wallace, and Mr. Macadam, and to others who had written him of their willingness to adopt some standard method. Referring to Mr. Tervet's remarks, this gentleman had, he said, struck out on an original line of work. Having been associated with him for some years, he was aware that a practical test on working principles was his (Mr. Tervet's) *forte*. Regarding pressure of scale till weight constant, he held to Mr. Redwood's opinion, as, of course, it was obviously unfair to press too long, lest scale might be pressed into the cloths. Referring to the suggested temperature of 70 F., he thought it would be more difficult to maintain it than that of 60 F., but apart from this, the latter was the temperature in general use. Additionally at a high temperature, if there was a large percentage of oil, a very great deal of hard paraffin might be carried out in solution. As to Mr. Tervet's practical test, the limited time at disposal in a works, or more especially a public analyst's laboratory, would obviate any sweating test or other approach to the working process. With reference to another member who had suggested a mechanical means of separation of water and dirt, such was quite unnecessary, as in melting in his tube the entire amount settled out in fifteen or twenty minutes. The remarks of Mr. King, manager of Messrs. Robin & Houston, candlemakers, were satisfactory as showing, from even the buyer's point of view, the *short* test was acceptable. In conclusion, he trusted that the ventilation of the subject would do good.

ADDENDUM TO MR. IRVINE'S PAPER ON EGYPTIAN PETROLEUM (THIS JOURNAL, VI. 130).

Mr. Irvine communicated to the Section that since reading the above paper he had received another letter from Captain Roberts, from whom he gathered that the quality of the oil varies, some samples being thick and viscid, others comparatively fluid. This pointed to evaporation or oxidation. So far, results did not point to Egypt becoming a rival of either America or Russia as a producer of petroleum.

Extract from Letter dated 9th March, 1887, at Suez:

"I regret that we are not able to report any important progress in the boring efforts at El Gemsah and Gebbel Teité. They have been working during some weeks; the bores are now in four different places, only a few yards from each other, and near the sea at El Gemsah; and I understand that the boring at Gebbel Teité is temporarily suspended. A fifth hole has been commenced about one-third of a mile inland of the four at El Gemsah, without results as yet. The workmen still believe that petroleum exists somewhere in the locality. It depends, however, on the decision of Government as to the duration of the work; they find the expenditure is becoming serious."

ON THE DETERMINATION OF MINUTE PROPORTIONS OF IRON, WITH SPECIAL REFERENCE TO ALUM AND SULPHATE OF ALUMINA.

BY R. R. TATLOCK, F.R.S.E., F.I.C., F.C.S.

The demand, on the part of Turkey-red dyers and calico printers, for alum and sulphate of alumina, as nearly as possible iron-free, has stimulated the manufacture in a very pure condition, as regards that metal, of these articles; the result of which is that both are now to be had of so high a degree of purity that the methods hitherto employed for estimating iron in these goods are no longer available, and, in many cases, do not give even approximately correct results. Some notion of the quality required and attainable may be formed from the fact that goods stated to contain only 0·001 per cent. (10 parts per million) of metallic iron may be rejected if the selling sample contained half that proportion. None of the methods hitherto published or in use, so far as I can ascertain, are capable of determining such small quantities with exactness, and frequently they are totally inapplicable on account of mechanical impurities, which render the solutions opalescent, thereby masking the colour struck by the reagent, all of these processes being based upon colorimetric observations. Nothing seems easier than to apply one of the delicate reagents commonly employed for the detection of iron in the ferric state, such as potassium thiocyanate (commonly called "sulphocyanide of potassium") or the corresponding ammonium compound, and from the depth of tint produced deduce the amount of iron present by comparison with standard ferric solutions. The disturbing influences, however, are numerous and great, and, to say the least, the sample and the standard would require to be treated under rigorously identical conditions, and, even then, results of the necessary degree of exactness are far from attainable.

There are two methods commonly in use for the detection and estimation of very small proportions of iron. One of these is based upon the depth of blue or green colour produced by addition of potassium ferrocyanide, and the other upon the intensity of the red colour obtained by addition of solution of an alkaline thiocyanate to acidified solution of the substance under examination.

In applying these reagents to the detection of iron in alum or sulphate of alumina, I find it is not uncommon to add them to the finely-powdered sample. This may be very useful as an empirical test to a manufacturer or consumer, will give a fair indication of purity as regards iron, and will even enable him to ascertain whether the article is equal to his accustomed standards; but as the depth of colour depends to a considerable extent upon the degree of fineness, it is only an approximative test, even for the comparison of two samples. It is quite valueless for determining the absolute proportion of iron in any sample, as the addition of standard solution of iron to the pure iron-free alum used for comparison would coat the outside of the small crystals superficially, and would thus be all available for the reagent, whereas the iron in the sample being tested would be for the most part locked up in the crystals, and to that extent, would not be amenable to the reagent.

The application of ferrocyanide for the determination of iron is not at all desirable, for various reasons. The tint is very variable—between a bright green and a full blue, even for the same proportion of iron, even when the other conditions are as nearly as possible equal, and comparison of intensity is thereby rendered unreliable; there is often a difficulty in keeping the prussian blue formed in perfect solution, even when oxalic acid is added; the composition of the blue produced cannot always be relied upon as uniform; and, lastly, it is not desirable to employ a reagent of which iron forms an essential constituent. On these grounds the use of this reagent for quantitative purposes is not to be recommended.

The employment of thiocyanate of potassium ($KSCN$), or of ammonium (NH_4SCN), for the determination of small quantities of iron, particularly in commercial aluminium salts, is, of course, common to all laboratories. It has been practised for many years, both for scientific and technical purposes, and as is well known, depends on the formation of the red ferric thiocyanate ($Fe_2 6SCN$), soluble in water, alcohol and ether. It is often recklessly referred to as "the sulphocyanide process," without reference to the marked effect upon the results of alterations in the working conditions, such as amount of reagent used, proportion of free acid present, presence of oxidisers employed to convert ferrous into ferric iron, etc.; all of which must have been noticed by such as have had to use this method largely, and without attention to which one observer might easily report five, or even ten times as much iron as another. I have been unable to find any account of experiments systematically made with the object of fixing the limits of interference from these and other ordinary causes, and have, in consequence, undertaken a series, of which the following is a statement:—In the course of the work it was observed that the well-known solubility of the red colour in ether was accompanied not only by a brightening of the tint from red to crimson, but by an increase in its depth, the same volume of the ether solution showing at least three times the intensity of colour, for the same amount of iron, that the water solution did. It occurred to me that this fact might be taken advantage of to increase the delicacy of the reaction in determining iron in commercial products, such as alum; while at the same time the uncertainty due to opalescence from mechanical impurities and from slightly coloured solutions would be obviated. It seemed requisite, therefore, to carry out four series of experiments, namely:—

1st Series—Iron in water solution, without ether extraction.
2nd ,, ,, ,, ,, with ,, ,,
3rd ,, ,, alum ,, without ,, ,,
4th ,, ,, ,, ,, with ,, ,,

The purity of the reagents, as regards iron, had to be ensured, and an examination soon showed that these, sold as pure, for analytical purposes, were quite unreliable, as they all contained a sufficient proportion of iron to vitiate the results.

Thiocyanate of ammonium, which was found to be more free from iron than the corresponding potassium compound, was obtained practically iron-free by acidifying very slightly with hydrochloric acid, crystallising twice, and washing several times with ether.

Sulphuric acid (for acidification) was obtained pure by dissolving the anhydride in the purest oil of vitriol obtainable, and distilling at a gentle heat into water.

Iron-free alum was obtained by five successive recrystallisations of the best Turkey-red alum procurable.

The purified reagents tested under all working conditions gave no indication of the presence of iron.

In the following trials the iron is the only quantity which remains constant throughout. The amount fixed upon was 0·00001grm. of Fe, as being approximate to that likely to be found in 1 grm. of good alum, or 0·001 per cent. The iron employed was in the form of iron-alum.

1st Series: *Iron in Aqueous Solution, without Ether Extraction*—

TABLE I.—IRON AND WATER ALONE.

NH_4SCN Employed.	Vol. of Solution.	Result.
1 equiv. = 0·000041grm.	20cc.	No colour.
2 ,, = 0·000082 ,,	,,	,,
10 ,, = 0·000410 ,,	,,	,,
100 ,, = 0·004100 ,,	,,	,,
1000 ,, = 0·041000 ,,	,,	,,
10,000 ,, = 0·410000 ,,	,,	,,
20,000 ,, = 0·820000 ,,	,,	,,

From these results it will be seen that neutral thiocyanate in any practicable proportion, gives no colouration with ferric salt, at least when only a small amount of iron is present. The following table shows the effect of free acid, that employed being sulphuric, as it is the only one likely to be met with in aluminium salts:—

TABLE II.—IRON, WATER AND FREE ACID.

NH_4SCN employed.	Free $\frac{N}{1}H_2SO_4$	Vol. of Solution.	Result.
1 equiv. = 0·000041grm.	0·1cc.	20cc.	No colour.
2 ,, = 0·000082 ,,	,,	,,	,,
10 ,, = 0·000410 ,,	,,	,,	,,
100 ,, = 0·004100 ,,	,,	,,	Faint rose.
1000 ,, = 0·041000 ,,	,,	,,	Decided ,,
10,000 ,, = 0·410000 ,,	,,	,,	Strong ,,
20,000 ,, = 0·820000 ,,	,,	,,	Stronger,,

These results show that it is only when 100 times the theoretical amount of thiocyanate is used that any colour at all is developed, even when the fluid is very decidedly acid, the tint increasing with the proportion of that reagent, up to 20,000 equivs., the free acid being a fixed quantity. The following table shows the results with 10 times the amount of free acid, all other conditions being equal:—

TABLE III.—IRON, WATER AND FREE ACID.

NH_4SCN Employed.	Free $\frac{N}{1}H_2SO_4$	Vol. of Solution.	Result.
1 equiv. = 0·000041grm.	1cc.	20cc.	No colour.
2 ,, = 0·003082 ,,	,,	,,	,,
10 ,, = 0·000411 ,,	,,	,,	,,
100 ,, = 0·004100 ,,	,,	,,	Distinct rose.
1000 ,, = 0·041000 ,,	,,	,,	Strong ,,
10,000 ,, = 0·410000 ,,	,,	,,	Stronger ,,
20,000 ,, = 0·820000 ,,	,,	,,	Strongest ,,

It is thus clear that with 5 per cent. of the entire volume of normal sulphuric acid in excess, no colour is obtained until 100 times the amount of thiocyanate is used, which is theoretically sufficient to convert all the iron present into ferric thiocyanate, and that the effect increases up to 20,000 equivalents, and probably beyond it. As no very great intensity was apparent beyond the 10,000 equivalents, a series of trials was made with this amount as a fixed, and the acid as a varying quantity, the results of which appear in Table IV. given on following page.

It is apparent from these results that the maximum effect is obtained by employing the normal acid in the proportion of one-tenth of the entire fluid bulk, and that no advantage is gained by adding more.

These results clearly demonstrate (1) that water solution of ferric salt, containing a small proportion of iron, such as is likely to be met with in saturated cold solution of commercial alum, does not give any colouration with neutral thiocyanate, even when the latter is used in enormous excess. (2) That the same negative result is obtained when free sulphuric is present up to 5 per cent. of the total volume of fluid of normal acid, even although ten times the theoretical amount of the thiocyanate be used. (3) That the intensity of colour increases with the amount of thiocyanate employed for the same quantity of free acid. (4) That the proportions of the reagents which give the best results are 10 per cent. of the total volume of fluid of normal sulphuric acid, and 10,000 times the proportion of thiocyanate required theoretically to produce ferric thiocyanate.

TABLE IV.—IRON, WATER AND FREE ACID.

NH_4SCN Employed.		Free $\frac{N}{1}H_2SO_4$	Vol. of Solution.	Result.
10,000 equiv. =	0·110000grm.	0·1	20cc.	Strong rose.
,,	,,	0·5	,,	Stronger ,,
,,	,,	1·0	,,	Still stronger rose.
,,	,,	2·0	,,	Full rose.
,,	,,	3·0	,,	Same as preceding.
,,	,,	4·0	,,	,,
,,	,,	5·0	,,	,,
,,	,,	10·0	,,	,,

2ND SERIES: *Iron in Water Solution, with Ether Extraction.*—Three series of trials were made, identical in every particular with those under Tables I., II., and III., and the water solution in each case shaken up with an equal volume of ether. The results were precisely the same as in these cases, excepting, of course, that the colour of the ether solution was altered from pale red to crimson, and intensified three-fold.

Another series was carried out on the basis of Table IV., which showed that the rose was developed in the third experiment instead of in the fourth as in the case of the water solution.

3RD SERIES: *Iron in Alum Solution, without Ether Extraction.*—In order to determine whether the same intensity of tint was produced in alum solution as in water solution, two trials were made with the most favourable proportions in each case, of thiocyanate (10,000 equivalents), and of normal acid (5 per cent. of total volume), all the conditions being equal except that one of the portions contained 2grms. of iron-free alum. It was at once seen that only half the intensity was produced in the latter case.

A series of trials was then made in the same manner to test the effect of variable proportions of free acid with constant quantities of all the other ingredients, the 2grms. of iron-free alum giving as nearly as possible a saturated solution. This led to the conclusion that no proportion of the normal acid, at least up to 50 per cent. of the total volume, had any appreciable effect in intensifying the colour. It follows, therefore, that while alum prevents the development of half the colour, it acts as an acid, but the effect is not appreciably intensified by any proportion, within the limits stated, of free acid, as is the case in water solutions of iron. These trials were made precisely on the basis of those in Table IV.

4TH SERIES: *Iron in Alum Solution, with Ether Extraction.*—A series of trials was now made in order to determine the effect of free acid, if any, on alum solutions, when the red colour was extracted with ether, all other conditions being the same as in Table IV. The results showed, contrary to what I expected, judging from those obtained without ether, that free acid materially increased the colour in the ether solution, an effect which is no doubt due to the fact that free sulphocyanic acid must be formed before the colour is produced at all, and that the ether removes it and the iron from the bleaching influence of the aluminium compound. It was further observed that no intensification could be produced by free acid beyond one-twentieth of the total final volume of fluid employed.

Ether extraction of the red ferric thiocyanate, therefore, has the following advantages, under all working conditions: It develops the red tint to triple intensity, besides increasing its brilliancy. It obviates the difficulty too commonly met with, of comparing colours in solutions which are opalescent from mechanical impurities, and in solutions which have naturally a brown or yellow tinge. It admits of the concentration of the iron, by the extraction of a large volume of ferric solution with a small volume of ether, and in this respect it is to micro-iron-determination what distillation is to Nesslerising. Finally, it does away with the injurious effect which aluminium salts have of preventing the development of the red colour, and thus admits of iron being estimated in alum with precision, by comparison with standard ferric solution in water, without the necessity of employing an absolutely iron-free alum for comparison.

In the working out of these experiments, I found that the scale upon which they were made was rather large for convenience and rapidity of execution, and have consequently been led to adopt only half the quantities all round, and I have now no hesitation in recommending the following process, which for simplicity, certainty, and rapidity is unsurpassed, if equalled, by anything in quantitative analysis; while for accuracy it is enough to say that it is capable of estimating iron in alum with the greatest ease to a unit of the fourth place of decimals (=·0001) per cent., or one part per million, and, with a little more trouble, to a tenth or even a hundredth of that amount.

PROCESS.

1. Make a standard solution of iron-alum ($Fe_2 3SO_4, K_2SO_4 + 24H_2O$) by dissolving 8·606grms. and making up with distilled water to one litre. As the alum contained 11·62 per cent of Fe, this will give a solution containing exactly 1grm. of metal per 1000cc. This solution should contain no free acid, and it will keep clear for weeks. Weaker standards become turbid, hence they must be made from this when required.

2. Place 1grm. of the finely-powdered sample in an ordinary stoppered sample-tube of about 30cc. capacity, and having three file marks—at 7½, 10, and 20cc. respectively. Add 1cc. of normal iron-free sulphuric acid, and make up to the lowest mark with pure water. Dissolve the alum by shaking the tube for a few seconds in a beaker of hot water, and when dissolved cool the solution again by holding the tube in cold water for a few seconds more. Add now 0·2grm. of iron-free ammonium thiocyanate, and make up to 10cc. with pure water.

3. Place 1cc. of the standard iron-solution of 1 in 100cc. flask, and make up to the latter volume with distilled water. Now place 1cc. of this reduced iron standard in a similar stoppered sample tube to that of 2, add 1cc. of the normal acid, make up to the lowest mark with water, add 0·2grm. of the thiocyanate, and make up to the 10cc. with water.

4. Finally, fill up both tubes to the 20cc. mark with ether and agitate them thoroughly. As soon as the contents settle compare the tints, and, if unequal, of course one or more further trials are made with greater or less quantities of standard iron-solutions

as may be necessary. Water takes up about $\frac{1}{10}$th of its volume of ether, and it so happens that this retained ether holds its proportion of the ferric thiocyanate; but as this is equally the case with the sample and with the standard, it is of little consequence; but in all delicate experiments the ether solution should be drawn off into graduated cylinders after adding a washing with an equal volume of ether, and compared there in any way most convenient.

Precautions.—The necessity for iron-free reagents has already been referred to. The thiocyanate may be prepared pure enough for all ordinary purposes by twice recrystallising the best obtainable in a very feebly acid solution, and washing with ether till the washings are colourless. Although the product is not absolutely iron-free, it appears so under working conditions. The acid may be obtained pure enough by distilling into water at a temperature much below its boiling point, of the purest obtainable oil of vitriol. Of course in all cases the reagents will be tested collectively by a blank experiment. The same precautions must be observed with regard to the vessels employed; all must be thoroughly digested with strong hydrochloric acid, and thoroughly washed before use; they should be kept under a glass shade, and employed for nothing else.

The operations should be conducted with as little light as possible, and certainly never in direct sunlight, or even in strong diffuse daylight. Berzelius in his "Traité de Chimie," vol. iv. p. 212, says that, according to Grotthus, a solution of ferric thiocyanate becomes as colourless as water by being exposed to the sun's rays for a few hours. I have found much more striking results, however, as a water solution of a medium port-wine colour was entirely bleached in one hour by a March sun at mid-day. I may add that the ether solution is also rapidly bleached by the sun's rays, but unlike the water solution it returns spontaneously within an hour if kept in a moderate light, and this is another advantage in the use of ether.

Oxidisers should be avoided, particularly peroxide of hydrogen, which, even in small quantity, destroys the red colour. Of course they would be required for ferrous iron, even small amounts, if the ether-extraction were not adopted, but not otherwise, as when the ether is employed the iron is completely oxidised to the ferric state, probably by the ozonisation of the air with which the fluid is agitated. So completely is this the case that it is of no moment whether the standard iron solution be made from a ferrous or a ferric salt, provided it contains the same proportion of metal.

The results of the following experiments demonstrate the last observation:—

Two trials were made with 0·00001 and 0·001grm. of iron respectively, in the ferrous state, both without and with ether-extraction, with the following results:—

Fe employed.	Without Ether, Fe found.	With Ether. Fe found.
0·00001grm.	0·000005grm.	0·00001grm.
0·001 ,,	0·00003 ,,	0·001 ,,

The composition of the mother-liquor from green alum shows that the greater part of the iron is already in the ferric state. A sample gave the results which appear in table on the next column.

It is not necessary in carrying out the process to take into account any free acid that may be present in alum or sulphate of alumina, as any proportion ever met with cannot interfere. During the agitation with ether a considerable quantity of the alum or sulphate of alumina is precipitated, but this is of no consequence, as all the iron remains in the solution.

	Per cent.
Sulphate of Alumina	10·39
Persulphate of iron	7·67
Protosulphate of iron	2·18
Protochloride of iron	1·29
Chloride of manganese	0·18
Sulphate of lime	Trace.
Sulphate of potash	0·38
Chloride of sodium	2·09
Chloride of magnesium	2·90
Hydrochloric acid (HCl)	7·33
Arsenious acid	0·67
Phosphoric acid	0·19
Water	64·73
	100·00
Specific gravity	1·3126
Ammonia and titanic acid	Absent.

A sample of Turkey-red alum gave 0·0005 per cent. of Fe by the above method, while a sample of high-class sulphate of alumina gave 0·0010 per cent.

In conclusion, it should be noted that it is desirable to keep as nearly as possible to 0·00004grm. of iron in 10cc. of fluid, as that is a good proportion for accurate colour-reading.

Journal and Patent* Literature.

I.—GENERAL PLANT, APPARATUS, AND MACHINERY.

Improvements in the Manufacture of Filters applicable for the Filtration of Water and other Liquids. J. R. Shearer, Stoke Newington. Eng. Pat. 734, Jan. 18, 1886. 8d.

THE improved filter consists of a hollow sphere or cylinder of unglazed porcelain contained in a case of the same form. The unfiltered water is admitted into the annular space between the septum and the case, and filters through into the interior of the septum. The surface of the septum is cleansed by means of a current of unfiltered water allowed to pass through the casing, a gyratory motion being imparted by suitably-shaped partitions.

Improvements in Apparatus for Cooling and Condensing Purposes. H. E. Newton, London. From E. Theisen, Leipsic, Germany. Eng. Pat. 2927, March 1, 1886. 8d.

THE object of this invention is the continuous use of a fixed quantity of cooling or condensing water for the purpose of refrigerating a liquid or condensing a vapour. This is effected by a modified form of "surface condenser," constructed of corrugated or convoluted tubes.

---

* Any of these specifications may be obtained by post, by remitting the cost price, *plus* postage, to Mr. H. Reader Lack, Comptroller of the Patent Office, Southampton Buildings, Chancery Lane, London, W.C. The amount of postage may be calculated as follows:—

If the price does not exceed 8d.	½d.
Above 8d., and not exceeding 1s. 6d.	1d.
,, 1s. 6d., ,, ,, 2s. 4d.	1½d.
,, 2s. 4d., ,, ,, 3s. 4d.	2d.

The heat absorbed by the cooling liquid is got rid of by exposing a thin film of the liquid to the air, by means of continuous rotating discs, by a series of plates alternately immersed in the liquid and exposed to the air, and by various other similar devices described at length, the essence of all of which is the continuous exposure of films or thin surfaces of the cooling liquid to the atmosphere.—C. C. H.

Improvements in and in Apparatus for Distilling Water. A. M. Clark, London. From P. Oriolle, Nantes, France. Eng. Pat. 3326, March 9, 1886. 11d.

The improvements consist in arranging a group of heating and condensing apparatus so that steam generated in the first of the series serves for the evaporation of a further quantity of water in the second of the series, and so on in a similar manner to the well-known method employed in *triple effet* vacuum pans. Five of such units are usually employed, the original source of heat being a steam boiler. The construction of the different parts of the apparatus exactly resembles that of some forms of feed-water heaters, in which the circulation of steam is insured by means of a small annular pipe placed in a larger heating pipe, the latter having one free closed end. The different elements or units are connected with pipes and cocks for the collection of condensed water and the circulation of steam and sea water undergoing distillation.—C. C. H.

Improvements relating to the Purification of Water and to Apparatus therefor. C. W. Burton, Nogent, and F. T. Moison, Mouy, France. Eng. Pat. 3731, March 16, 1886. 11d.

This specification describes at length various mechanical contrivances for the addition of purifying or precipitating reagents to a water, and the separation of the precipitate resulting. This is primarily effected by means of an hydraulic balance, which measures the water undergoing purification, and by its oscillation tips a measured quantity of the reagent into the water thus measured. The precipitate is separated in a decanting apparatus, several forms of which are described at length.

—C. C. H.

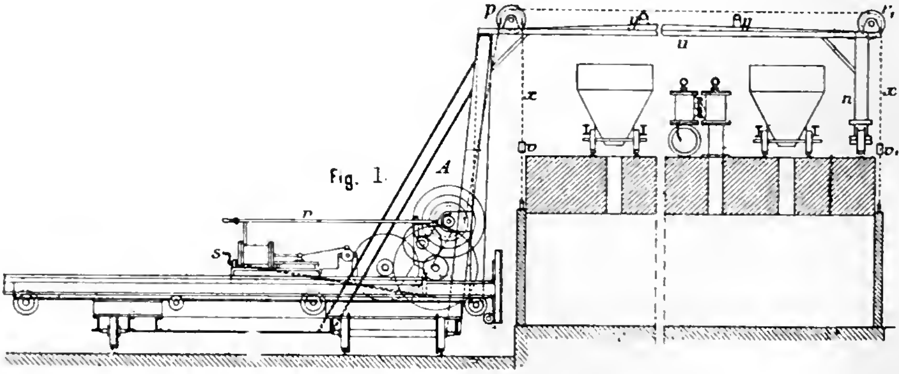

Fig. 1.

Improvements in Filtering Apparatus. H. E. Newton, London. From W. M. Deutsch, New Jersey, U.S.A. Eng. Pat. 16,994, Dec. 28, 1886. 11d.

The improvements refer to that description of filter which consists of a filtering bed of finely divided material placed in a cylinder, through which the water is forced, the impurities being removed from time to time by reversing the flow of water through the apparatus. They consist—(1) In dividing the lower part of the bed into four sections by vertical axial partitions, in order to concentrate the force of flow of the cleansing water. (2) Providing washing-out pipes for a reversal of flow at two or more different depths in the bed. (3) Providing a receptacle from which the incoming water can take up a precipitating material, such being regulated by holes in the outer periphery arranged in a "gridiron" fashion. The patentee makes fifteen claims.—C. C. H.

II.—FUEL, GAS, AND LIGHT.

Improvements in Coke Ovens. Dingl. Polyt. J. **262**, 520—523.

To facilitate the removal of the charge from horizontal coke ovens, Roechling Bros. have devised an arrangement (Ger. Pat. 35,407, Sept. 2, 1885) which admits of the simultaneous opening of both working doors of each chamber from one side of the oven. The contrivance illustrated in Fig. 1, is attached to the locomotive apparatus used for removing the coke from the oven. The drawing shows also that the ovens are charged by bringing the trucks, loaded with the material to be coked over the charging holes, and dropping the contents into the respective chambers by withdrawing the bottom of the truck. Quaglio (Ger. Pat. 36,097, August 29, 1885) has devised an arrangement consisting in loading each chamber from its side, a truck being used which is of the same length as the coking chamber, and travels on a railway facing the coke oven. The truck has two side flaps *a* (Figs. 2 and 3), a movable bed-plate *b*, and two movable ends *c* and c_1, forming a square box, the dimensions of which are somewhat less than those of the chambers. This box rests on a trolley *d*, worked by a winch *h*. The charge is compressed in the truck by a specially-constructed stamping arrangement, and is then loaded into the oven by bringing the truck in front of the chamber A, turning the flaps of the box aside, and drawing the box with its bed and contents into the chamber. The ends c and c_1 are then removed, and the furnace doors B lowered, sufficient space being, however, left for withdrawing the bed plate. In Fig. 2, C represents a coke ramp. To economise space the removal of the coke may be effected by the machine used for loading the charge, as illustrated in Fig. 4. Collin, of Dortmund, has patented a vertical coke oven (Ger. Pat. 36,518, Aug. 18, 1885), the essential feature being the production of firm coke in an apparatus which occupies but little space compared with its working power. In Figs. 5 to 7 the charge is introduced into the chambers O, through the openings F. The coke is removed by withdrawing the horizontal bed plates T. The gases from O proceed through the apertures *a* into the flue C; they then pass through the openings V, into the lateral flues, ascend in W in a spiral direction (see Fig. 7), and proceed through *v* into the upright passage H and the flues H, H_1, and thence into the main flue C. The air supply proceeds from the flue L, which is parallel to G, through the channels Z into V, where it mixes with the gases from C. By this construction of the flues the heat, which is radiated by the outer walls of the oven, assists the coking process to a considerable extent. To recover the bye-products from the distillation gases a condensing apparatus may be interposed between

Fig. 2.

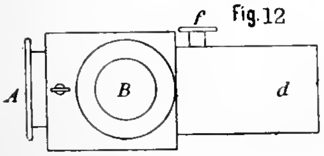

Fig 8

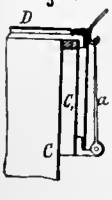

Fig 10

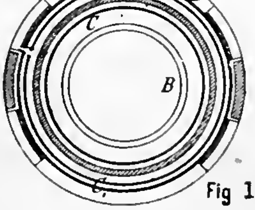

C and the subsequent system of flues. Quaglio has patented a water seal (Ger. Pat. 36,357, Nov. 7, 1885), for coke ovens with recovery of by-products, which is illustrated in Figs. 8 to 10. A pipe C is placed over the gas exit pipe B, the upper end of which is sealed by the water tank E, and the lower part by A. The top of C is closed by the cover D. When C is raised the exit pipe B is open, whilst on lowering it all communication with the coking-space is stopped. To prevent the possibility of leakage through tar, carbonaceous matter, or pitch, adhering to the plugs or seatings of gas stop-cocks, Schmalz (Ger. Pat. 37,182, April 14, 1886) has devised an arrangement represented in Figs. 11 and 12. A is the gas inlet, B leads to the condenser; the part ab is made round, so that the tar or pitch from A may be deposited in ab, and pushed forward to d, by introducing a long chisel through a plug screwed into the cover C; the seal effected by the partition e, and the water from A prevents the escape of gas at d, the excess of water being run off through f. When f is closed, the water from A rises to d, and thereby seals the pipe B. To repair the brickwork of the chambers of coke ovens without stopping the process, Kleist and Zeller recommend the use of an instrument illustrated in Fig. 13. It consists of a cylinder a, with mouthpiece b, the piston c, piston rod d, shaft f, and bush g. The cylinder is charged with mortar made of fire-clay, and placed with its mouthpiece b in or near the wall or joint to be filled up. The mortar is then pressed into the joint with the piston c.

Wolf's Safety Lamp. Oesterr. Ztschr. f. Berg. u. Hüttenw. 1886, 472—473.

This is a benzene lamp so contrived that it can be lighted whilst closed. The benzene used gives a bright light compared with oil, and just enough is added to saturate the porous material in the lamp. The flame can be regulated by a screw at the bottom of the apparatus, and extinguished at will. The great advantage of the lamp is that it can be lighted without opening it; this is done by a little friction machine in the lamp for firing caps, which are attached to a strip of paper and inserted in a coil. By touching a button under the lamp one of the caps is fired and so lights the vapours of benzene coming off from the wick of the lamp. The coil contains 75 caps, only costs a few pence, and the apparatus is practically perfect as regards safety. The lamps have been largely used with great success in several mines near Dortmund.—E. E. B.

III.—DESTRUCTIVE DISTILLATION, TAR PRODUCTS, Etc.

Production of Light Hydrocarbons from Heavy Paraffin Oils, Crude Petroleum, Petroleum Residues, and the Tar obtained in the Manufacture of Oil Gas. Chem. Zeit. **10**, 1622.

This process, which is patented by Riebeck, consists in subjecting the above oils to distillation in cast-steel retorts under a pressure of several atmospheres, whereby the high boiling hydrocarbons are decomposed with formation of a large proportion of valuable light oils, the residue being used for the manufacture of lubricating oils or asphalt making. The pressure to be applied depends upon the character of the oil to be treated—*e.g.*, the tar oils from brown coal give the best results when subjected to a pressure of from 3 to 6 atmospheres, whilst petroleum and its residues requires a pressure of 2 to 4 atmospheres, and the tar from oil gas 4 to 6 atmospheres. The following are the results of some experiments made on a large scale to illustrate the advantages of this process. A dark-coloured heavy paraffin oil was used, having a sp. gr. of 0·912 at 17·5°, a viscosity of 2·5, and yielding only 15 per cent. of distillate below 300°. The oil was distilled at a pressure of 3 atmospheres. The distillate formed a brown mobile liquid having a sp. gr. of 0·800—0·820 at 17·5°, and yielding on rectification a colourless burning oil of high illuminating power, the sp. gr. of which was 0·815 and the flashing point 30°. The constitution of the distillate was the same whether 30 or 80 per cent. of the original oil was distilled off; the residue, however, varied with the percentage of distillate obtained. By taking off from 25—30 per cent. the residue formed a good lubricating oil of 0·930—0·950 sp. gr. and a viscosity of 7—10. When 50 per cent. of the oil was distilled off, the residue formed a black pitchy mass of 1·005 sp. gr., whilst in the case of 80 per cent. of distillate, a coky asphalt remained in the retort.

—D. B.

The Blue Colouration of Ammonium Sulphate. Frère. Les Corps Gras Industr. **13**, 161.

A BLUE colouration of ammonium sulphate is due to cyanides in the ammoniacal gas-liquor, and if a white-finished product is required the ammonia still must be connected with the acid tank by a leaden pipe. An iron pipe invariably gives a blue-coloured product. The acid itself rarely contains so much iron as to colour the finished product.—S. H.

Improvement in Petroleum Oils. E. Phillips, London. Eng. Pat. 5801, April 28, 1886. 4d.

THIS invention consists in tinting petroleum with a distinguishing colour by adding a small quantity of a dyeing material, preferably aniline scarlets and violets. Consumers are thereby enabled to ascertain at a glance the quality of the petroleum supplied to them, however small the quantity may be.—D. B.

IV.—COLOURING MATTERS AND DYES.

Researches on the Constitution of Azo and Diazo Derivatives. I. Diazo-amido Compounds. R. Meldola and F. W. Streatfeild. J. Chem. Soc. **1887**, 102—118.

IN a former communication the authors have shown that the hydrogen atom in the group $—N_2.NH—$ in diazo-amido compounds can be readily replaced by an alkyl radicle; they described the ethyl derivative of paradinitrodiazoamidobenzene as a type of these compounds. In the present paper the authors continue their investigations on other diazo-amido compounds, with special reference to the decomposition of these bodies by means of acids.

By the action of diazotised metanitraniline upon paranitraniline a substance was obtained crystallising from alcohol in yellow needles, melting with decomposition at 211°. The analyses gave results which agreed with the formula $NO_2C_6H_4.N_2.NH.C_6H_4NO_2$. In its general properties it agrees with the isomeric paradinitro-compound, although not of such an acid character. On complete reduction it gives a mixture of meta- and paraphenylenediamine. Decomposed with hydrochloric acid at 100°, a mixture of para- and metanitrochlorobenzenes, in addition to a mixture of para- and metanitranilines, was obtained. The ethyl derivative was prepared in a similar manner to the corresponding para compound, and was obtained in small yellow needles melting at 148°. On analysis it gave numbers agreeing with the formula $NO_2.C_6H_4.N_2.N(C_2H_5)C_6H_4NO_2$. Heated with hydrochloric acid to 100° it gave a mixture of meta- and paranitrochlorobenzene, also ethylmeta- and ethylparanitraniline.

By the action of one molecule of sodium nitrite upon two molecules of metanitraniline *metadinitrodiazoamidobenzene* was prepared (first obtained by Griess, *Ann. Chem. Pharm.* 121, *272*). It crystallises from alcohol in straw-coloured needles melting at 194° (195·5°, Griess). Analyses agreed with the formula $NO_2.C_6H_4.N_2.NH.C_6H_4.NO_2$. It differs from the para and the unsymmetrical derivative in being very much less acid in character. On decomposition with hydrochloric acid it gives metanitrochlorobenzene and metanitraniline. Nothing of a phenolic nature was obtained. The ethyl derivative was prepared and obtained in pale yellow needles melting at 119°. When decomposed with hydrochloric acid, ethylmetanitraniline and metanitrochlorobenzene were obtained. The authors find that the compound obtained by the action of diazotised paranitraniline upon metanitraniline is identical with that obtained by the action of diazotised metanitraniline upon paranitraniline, thus confirming the observations of Griess, Sarauw, and Nölting and Binder upon other diazo-amido compounds. From theoretical considerations the authors come to the conclusion that isomeric transformation may take place. In order to throw light upon this question, the authors have studied the action of diazotised nitranilines upon ethylnitranilines. Diazotised metanitraniline gives with ethylparanitraniline a yellow crystalline body, melting at 174—175°; isomeric with that obtained in an earlier part of the work, melting at 148°. Treated with hydrochloric acid it gives ethylparanitraniline and metanitrochlorobenzene. When diazoparanitrobenzene chloride acts upon ethylparanitraniline a compound is obtained which was recognised as paradinitrodiazo-ethylamidobenzene (*J. Chem. Soc. Trans.* xlix. 630). By the action of paranitraniline upon ethylmetanitraniline a body was obtained, crystallising from alcohol in orange-red needles melting at 187°. This body appears to be an amido azo compound, but is undergoing further investigation. Diazotised metanitraniline gives with ethylmetanitraniline a compound identical with that obtained by the direct ethylation of metadinitrodiazo-amidobenzene. By the action of benzyl chloride upon the potassium salt of paradinitrodiazo-amidobenzene, paradinitrodiazobenzylamidobenzene is obtained, crystallising from benzene in yellow needles melting at 190°. Heated with hydrochloric acid, paranitrochlorobenzene and benzylparanitraniline are obtained. Benzylparanitraniline crystallises from alcohol—in which it is very soluble—in golden-yellow leaves melting at 142—143°. It is a weak base. Treated with nitrous acid it gives a nitrosamine, crystallising from acetic acid in lustrous straw-coloured needles melting at 107·5°. The corresponding metadinitrodiazobenzylamidobenzene was obtained, after crystallising from alcohol, in pale-yellow needles melting at 142°. Decomposed with hydrochloric acid it gives metanitrochlorobenzene and benzylmetanitraniline; this last substance treated with nitrous acid gives a nitrosamine, which was obtained as an oil. The benzyl-derivative of the unsymmetrical dinitrodiazo-amido-compound was also prepared. It was obtained in microscopic yellow needles insoluble in alcohol, very soluble in benzene, and melted at 180°. Decomposed with hydrochloric acid it gives a mixture of benzylpara- and benzylmetanitraniline, with the corresponding nitrochlorobenzenes. In conclusion, the authors discuss briefly the bearing of the experimental evidence upon the constitution of the foregoing diazo-compounds, and propose to continue their investigations.—R. M.

Manufacture of the Eosin Colouring Matters. O. Mulhäuser. Ding. Polyt. J. **263**, 49—58 and 99—107.

THE author gives a long and detailed description of the preparation of these dyestuffs, of which the following is a summary:—

Fluorescein.—This body, which itself has little tinctorial value, is the starting-point of all the eosin colouring matters, which are derived from it by replacement of hydrogen by Br, I, NO_2, etc. It is prepared by heating together resorcinol and phthalic anhydride with or without addition of zinc chloride.

(*a*) 17½kilos. of phthalic anhydride are added with stirring to 25kilos. of melted resorcinol contained in an enamelled pot set in an oil bath, which is heated to about 160°. After heating for about 1½ hours at 180°, the reaction commences, and lasts for about 40 minutes, the melt boiling vigorously. The heating is continued for 23—30 hours at 200—205°, with occasional stirring. The crude fluorescein thus obtained is boiled in a tub with 500 litres of water and 50kilos. of aqueous $NaOH$ of 36° B. The volume of the solution is made up to 1000 litres and filtered. The fluorescein is precipitated from the filtrate by addition of 90kilos. of hydrochloric acid, washed by decantation, and dried. The yield is about 36kilos.

(b) 8kilos. of powdered zinc chloride are quickly added to a fused mixture of 25kilos. of resorcinol and 17kilos. of phthalic anhydride heated to 180°. The pot is covered up and stirred with an iron rod for about 5 minutes. The reaction then sets in, and the mixture becomes nearly solid. The heating is continued for about 10 hours at 190—200 , and the product is purified as in *(a)*.

Tetrabromofluorescein.—The sodium and ammonium salts of tetrabromofluorescein come into commerce under the names of *Eosin A*, *Eosin B*, *Soluble eosin*, etc.

(a) 32kilos. of bromine are dissolved in 60kilos. of aqueous $NaOH$ (36° B.) diluted with 150 litres of water, and the solution boiled to decompose hypobromite. 16kilos. of fluorescein are dissolved in 25kilos. of aqueous $NaOH$ (36° B.) diluted with 150 litres of water. The two solutions are mixed in the cold, treated with 140kilos. of hydrochloric acid, and heated to boiling. The precipitate of tetrabromofluorescein is washed by decantation and dried. The yield is about 30kilos. It is converted into the ammonium salt by spreading it out on trays and exposing it to the action of dry ammonia gas until a test dissolves in water to a clear solution (yield : 31·8kilos. from 30kilos. of the acid). The sodium salt is prepared by adding exactly the right quantity of $NaOH$ solution (determined by experiment) to 60kilos. of tetrabromofluorescein, suspended in 210kilos. of boiling alcohol. On cooling, the pure sodium salt crystallises out (yield = about 57kilos.).

(b) 24kilos. of bromine are slowly run into 10kilos. of fluorescein, suspended in 80kilos. of cold alcohol. The bromination is complete in 15 minutes; the pans are then covered up and allowed to stand for three or four days. The precipitate is washed with alcohol and dried. The yield of tetrabromofluorescein by this method is about 17kilos. It is converted into the sodium or ammonium salt in the manner described above.

Dibromofluorescein (eosin-orange).—10kilos. of fluorescein are suspended in 80kilos. of cold alcohol and treated with 12kilos. of bromine. The dibromofluorescein remains dissolved in the alcohol, and is precipitated by addition of about 100 litres of water. The precipitate, after being washed, is dissolved in 200 litres of water and 20kilos. of aqueous $NaOH$ (36° B.), and when cold re-precipitated by 40kilos. of hydrochloric acid. The yield of washed and dried dibromofluorescein amounts to 15½kilos. It is converted into the sodium salt by exact neutralisation with $NaOH$, and evaporated to dryness (yield = 17kilos.).

Ethyltetrabromofluorescein.—The potassium salt of this acid is used for silk-dyeing under the names of *Spirit-eosin*, *Primrose à l'alcool*, *Eosin à l'alcool*, *Rose J.B. à l'alcool*, etc. It is prepared by brominating fluorescein in boiling alcohol, by which means it is simultaneously ethylated. 52kilos. of bromine are allowed to run, through a glass tube dipping below the surface, into 20kilos. of fluorescein suspended in 80kilos. of boiling alcohol (96 per cent.) contained in a steam jacketed enamelled pressure vessel provided with a leaden cohobator and mechanical stirrer. As soon as all the bromine has been added, which takes about 50 minutes, the two cocks are closed, and the mixture heated under a pressure of 1½ atmospheres for three hours. When cold the precipitate is separated, washed with alcohol, then with water, and finally exactly neutralised with KOH in hot 36 per cent. alcohol (40kilos. of alcohol + 68kilos. of water). On cooling, the pure potassium salt crystallises out, whilst a certain amount of accompanying tetrabromofluorescein remains in solution. The yield of pure spirit-eosin is about 25kilos.

Dibromodinitrofluorescein.—The alkaline salts come into commerce as *Eosin scarlet*, *Ros des Alpes*, *Safrosin*, *Lutécienne*, *Daphnin*, etc. It is prepared by simultaneous nitration and bromination of fluorescein in alcoholic solution, or by nitration of dibromofluorescein in acetic acid or aqueous solution.

(a) To 7kilos. of fluorescein finely suspended in 60kilos. of alcohol 7kilos. of nitric acid (40° B.) are slowly added, and directly afterwards 7¼kilos. of bromine. After standing till next day the precipitate is washed with 30kilos. of alcohol, boiled with water two or three times and dried. Yield = 12½kilos.

(b) 4kilos. of finely-ground sodium nitrate is stirred into a paste composed of 30kilos. of tetrabromofluorescein and 25kilos. of glacial acetic acid. The mixture is heated on a water-bath. At 70—80° the reaction sets in, and is completed by six or eight hours' heating. The product is boiled for 10 minutes with 500 litres of water, and the precipitate washed by decantation. Yield = 29kilos.

(c) A cold, previously boiled, solution of 12kilos. of bromine in 20kilos. of aqueous $NaOH$ and 50 litres of water is mixed with a cold solution of 10kilos. of fluorescein in 13kilos. of aqueous $NaOH$ (36° B.) and 200 litres of water. The mixture is acidified with 40kilos. of sulphuric acid (40 B.) and 30kilos. of nitric acid (40° B.) slowly run in. Finally, the mixture is heated to boiling on a water-bath for five or six hours. The yield of washed and dried precipitate is 19½kilos. The product obtained by either of these processes is converted into the ammonium salt by means of gaseous ammonia, or into the potassium or sodium salt by neutralisation with a rather insufficient quantity of KOH or $NaOH$, by which means the impurities remain undissolved.

Tetra-iodofluorescein.—The sodium and ammonium salts are used for silk, cotton, and paper dyeing under the names of *Erythrosin B*, *Pyrosin B*, *Iodeosin B*, *Dianthin*, *Rose B à l'eau*, *Primrose soluble*, *Blue shade eosin*, etc. 6kilos. of fluorescein are dissolved in a hot mixture of 8kilos. of aqueous $NaOH$ (36° B.) and 60 litres of water. 24kilos. of iodine are dissolved in 27 to 28 kilos. of $NaOH$ (36° B.), diluted with 60 litres of water, and the solution boiled. The two solutions are mixed and acidified with 25kilos. of acetic acid. The mixture is boiled, neutralised with 17kilos. of aqueous $NaOH$ (36° B.), and re-precipitated by adding 25kilos. of hydrochloric acid diluted with 25 litres of water. The precipitate is boiled, separated, boiled several times with dilute HCl, lastly with water alone, and dried. The yield is about 15kilos. It is converted into the ammonium salt by dry ammonia gas.

Di-iodofluorescein.—Erythrosin G or Dianthin G, which consist chiefly of the di-iodo-derivative, is prepared in the same way as the preceding, except that only 16kilos. of iodine are used for 6kilos. of fluorescein. The yield is about 13kilos.—A. G. G.

On the Industrial Production of Resorcinol. Dr. Otto Mühlhauser. Dingl. Polyt. J. **263**, 154.

THE author gives a detailed account both of the method and plant employed for the production on a large scale of resorcinol. Benzene monosulphonic acid is first prepared by treating 60kilos. of pure benzene (free from thiophen) with 300kilos. of sulphuric acid of 67° B. in a cast-iron pan, provided with an agitator and a leaden reflux condenser. To bring about the reaction, the mixture is continuously stirred and a very gentle heat applied. After ten hours the reaction ceases. For the purpose of preparing the disulphonic acid, the monosulphonic acid is treated with an excess of sulphuric acid, and run into another cast-iron pan, similarly furnished with agitator and condenser, which, however, is turned downwards. The mass is mixed with 85kilos. of powdered and perfectly dry sodium sulphate, and heated in an oil-bath, so that the temperature of the mixture remains for eight hours at 225°. At first, benzene distils over and is collected, while sulphurous acid is evolved. The sodium salt of the sulphonic acid is then prepared in the usual manner and thoroughly dried. The yield is about 200kilos. 250kilos. of caustic soda and 10kilos. of water are now melted over the direct flame in a cast-iron pot, until the molten mass is so hot as not to solidify on the addition of the sodium salt. When a little common salt thrown in, dissolves rapidly with a hissing sound. the needed temperature has been reached, and after setting the agitator in motion, 125kilos. of the dry sulphonate are quickly introduced. When the mass has become brown and almost ceased to work, it is cooled, broken up and acidified with hydrochloric acid. The resulting liquor is now extracted four times with 100kilos. of purified amyl alcohol. After distilling off the latter with steam, the residue is evaporated to dryness in enamelled pans. To purify the resorcinol thus obtained, it is distilled in vacuo; water and phenol going over first. At about 190° the pressure should be decreased to 630mm. On heating further, the resorcinol begins to boil and distils over. The yield is 20—23kilos. of the pure product, or, from the numbers the author gives, about fifty per cent. of the theoretical yield on the benzene employed.—A. R.

Manufacture of a Yellow Dyestuff from Gallic Acid. Dingl. Polyt. J. **263**, 205.

THE dye, which can be fixed on the mordanted fibre like alizarin, and which has been termed "Galloflavin," is obtained by the action of air—*i.e.*, oxygen—on alkaline solutions of gallic acid. The process of oxidation depends on the amount of alkali present, for whereas it proceeds too quickly if the alkali be used in excess, the oxidation can be moderated by diminishing the quantity of alkali. In practice, 5 parts of gallic acid are dissolved in 80 parts of alcohol of 96° Tr. and 100 parts of water. The cooled solution is gradually mixed with 17 parts of a potassium hydrate solution of 30° B., stirring all the while, and never allowing the temperature to rise above 10° C. It is then exposed to the action of oxygen, either by blowing air through it or agitating it briskly. The progress of the oxidation shows itself by the liquor assuming at first an olive-green or greenish-brown colour, until finally a crystalline precipitate separates out. When the amount of this precipitate no longer increases, the operation is finished. The mass of crystals is quickly filtered, dissolved in warm water, decomposed with hydrochloric or sulphuric acid, and boiled, when the dye is precipitated in the state of glittering greenish-yellow plates. These are washed, and can then be applied for dyeing or printing. Galloflavin dyes cotton mordanted with alumina greenish yellow, which turns into a very brilliant yellow by the treatment with tin crystals. The chromium-lake of galloflavin is distinguished by being especially proof against soap, air or light.—S. H.

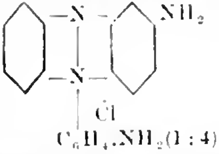
Constitution of Safranine. O. N. Witt. Ber. **19**, 3121—3124.

THE two formulæ lately proposed for this colouring matter, $C_6H_5.N\begin{array}{l} C_6H_3-NH_2Cl \\ \quad | \\ \quad N \\ \; / \\ C_6H_3-NH_2 \end{array}$ by Andresen, and $C_6H_5.\underset{Cl}{N}\begin{array}{l} C_6H_3-NH_2 \\ \qquad \diagdown N \\ \diagdown C_6H_3-NH_2 \end{array}$ by Bernthsen, are both open to the objection that being symmetrical they do not explain the unquestionable existence of pairs of isomeric mono- and (tertiary) di-alkylised derivatives. They are also both based upon the assumption that the third amine group becomes attached to the first-formed di-*p*-amidodiphenylamine by removal of both hydrogen atoms from its NH_2 group. This the author considers to be contrary to analogy with what generally takes place in such reactions, the hydrogen usually being removed half from the nitrogen and half from the carbon of the entering amine. Applying this view, leuco-safranine would be formed thus:

$$\begin{array}{lcl} H_2N.C_6H_3 & \boxed{H \quad H} & NH \\ \qquad | & & \; | \\ H_2N.C_6H_4.N & \boxed{H \qquad H} & C_6H_4 \end{array}$$

$$= \begin{array}{l} \qquad\quad H_2N.C_6H_3-NH \\ \qquad\qquad\qquad\; | \qquad\quad | \\ H_2N.C_6H_4.N\text{———}C_6H_4 \end{array} + H_4.$$

This gives for phenosafranine an unsymmetrical formula:



which admits of isomeric alkylised derivatives. Like the formulæ of Bernthsen and Andresen, it represents safranine as an azine, and only differs from these formulæ with respect to the position of one NH_2 group.—A. G. G.

Constitution of Safranine. R. Nietzki. Ber. **19**, 3163—3166.

THE author supports Witt's formula for this body. The non-identity of the two dimethylsafranines, (*a*) from *m*-dimethyl-*p*-phenylenediamine and 2mols. of aniline, (*b*) from *p*-phenylenediamine, dimethylaniline, and aniline, is shown by a microscopic examination of their crystalline nitrates. If, as is assumed in the formulæ of Andresen and Bernthsen, in the third amine the NH_2 only takes part in the reaction, all the homologues of aniline should give safranines with equal ease; this, however, is not the case. By oxidation, in conjunction with *p*-di amidodiphenylamine, safranines were obtained from the two xylidines $C_6H_3(NH_2)(CH_3)_2$(1 : 2 : 4) and (1 : 3 : 4), and from solid cumidine $C_6H_2(NH_2)(CH_3)_3$ (1 : 2 : 4 : 5): whilst xylidine (1 : 2 : 3) gave only a trace and the other three xylidines (1 : 2 : 6), (1 : 2 : 5), and (1 : 3 : 5), together with isocumidine (1 : 3 : 4 : 5) and mesidine (1 : 2 : 4 : 6) gave none. Thus the position of the methyl groups in the nucleus greatly influences the reaction.—A. G. G.

Pyrogenetic Formation of Phenazine. A. Bernthsen. Ber. **19**, 3256—3258.

IN a previous communication (this Journal, 1886, 317) reference was made to the formation of a basic oil when the vapour of aniline is passed through a tube heated to redness. Attempts to convert this base into phenazine, a compound of the constitution $C_6H_4\!<\!\begin{array}{c} N \\ | \\ N \end{array}\!>\!C_6H_4$, were, however, unsuccessful, probably owing to the want of information concerning the distinctive properties of this substance. Further researches having shown that phenazine is possessed of characteristic properties (this Journal, 1886, 661), the author thought it expedient to reinvestigate the product formed by passing aniline vapour through a red-hot tube. The basic mixture thus obtained was heated with successive portions of dilute hydrochloric acid, the solution precipitated with ammonia, the precipitate extracted with ether, and the extract digested with dilute hydrochloric acid. The ethereal solution was evaporated, the residue dissolved in hydrochloric acid, and the solution precipitated with ammonia. On subliming the precipitate, light yellow lustrous needles were obtained, possessing all the properties which characterise phenazine. This result, therefore, proves the possibility of obtaining phenazine from aniline by a reaction analogous to the pyrogenetic formation of anthracene from toluene.—D. B.

Improvements in the Manufacture of Azo-dyes and Benzidine and Tolidine Monosulphonic Acids. J. Y. Johnson, London. From the Actiengesellschaft Farbenfabriken vorm. F. Bayer and Co., Elberfeld, Germany. Eng. Pat. 3198, March 6, 1886. 6d.

IN order to prepare the new monosulphonic acid described in this specification, benzidine or benzidine-sulphate is heated with two parts of monohydrated sulphuric acid to 170° for about 1½ hours. The product is diluted with water and the sulphonic acid thus precipitated collected by filtration and purified by solution in alkali, filtration, and reprecipitation by acid. The acid is nearly insoluble in water, and differs from the other sulphonic acids of benzidine in that its salts are decomposed by acetic acid. The tetrazo compound of the new acid is said to differ from that of the benzidine-disulphonic acids in being soluble in water and giving azo-dyes of a bluer shade than tetrazodiphenyl. The preparation of the azo-dyes is conducted in the usual way, yellow colouring matters being produced by the action of the tetrazomonosulphonic acid upon aniline, toluidine, xylidine, mesidine or their sulphonic acids; phenol, resorcinol, the naphthols and their sulphonic and carboxylic acids give colours varying from red to violet. As examples of the method of manufacture, the inventors describe (1) the preparation of an alizarin-like red, suitable for cotton, formed by the action of one molecule of the tetrazosulphonic acid upon two molecules of β-naphthylamine-β-monosulphonic acid, and (2) a bluer shade of red formed by the action of one molecule of the tetrazosulphonic acid upon one molecule of β-naphthylamine, and then upon a second molecule of β-naphthylamine-β-monosulphonic acid.—R. M.

Improvements in the Manufacture of Colouring Matter. T. Maxwell, Govan, and J. Young, Milton-of-Campsie. Eng. Pat. 4687, April 3, 1886. 4d.

This invention relates to improvements in the manufacture of colouring matters adapted for dyeing fibrous substances by the dry process. The dyes used are coloured native earths, such as raw sienna or native earths, which assume a coloured state by calcining, or mechanical or chemical treatment, as burnt sienna. Inorganic coloured precipitates or lamp black may also be used. These colouring matters are, when necessary, reduced to a fine powder, and mixed with a non-saponifiable or other oil by stirring until the whole mass is as homogeneous as possible. The mixture is then sifted to free it from grit, the action at the same time furthering the more equal diffusion of the oil amongst the coloured particles. —D. B.

V.—TEXTILES: COTTON, WOOL, SILK, Etc.

Improvements in Treating and Preparing Tussur and other Wild Silk Cocoons, and in the Application of the Silk obtained therefrom to the Manufacture of Lace, Knitted Warp, and other Fabrics. H. Birkbeck, London. From T. F. Peppé, Shahabad, Bengal, India. Eng. Pat. 3937, March 20, 1886. 6d.

The improved treatment consists in heating the cocoons under pressure in a solution containing glycerin and carbonate of soda, whereby they are rendered soft. During this operation they are kept separate by wrapping them in cloth-paper or wire gauze. The threads are then conducted to the pliers of a spinning frame, on which they are wound. The inventor claims that by his process, Tussur and similar silks can be made so fine as to render them suitable for making lace of the finest description.—E. J. B.

The Mechanical and Chemical Treatment and Preparation of the Plant botanically termed Bauhinia Vahlii. J. H. Wilson, Camberwell. Eng. Pat. 12,532, Oct. 2, 1886. 4d.

The inventor separates the fibres by passing the dried stems through rollers of peculiar construction. They are then treated with chlorine gas or alkaline hypochlorites. —E. J. B.

VI.—DYEING, CALICO PRINTING, PAPER STAINING, AND BLEACHING.

Improvements in Dyeing Fabrics and in Apparatus used for that Purpose. W. G. White, London. Eng. Pat. 1750, Feb. 5, 1886. 8d.

The inventor refers to Eng. Pat. 3047, 1879, and 14,020, 1884, where he describes a system of colour printing, in which the printing block employed is built up of suitably prepared materials, containing the various colours required by the design, and imparts a portion of its own substance to the fabric to which it is applied. The present invention applies this system of printing to the dyeing of fabrics in plain colours. For this purpose the colouring material is cast on to a number of rollers, so as to form a cylindrical coating round each of them. The rollers are then mounted in bearings and driven at one speed. The fabric to be dyed, after being mordanted and moistened with a suitable damping liquid, is laid round one of the colour rollers so as to bring one surface of the fabric in contact with that roller, then round the next roller so as to bring the other surface of the fabric in contact with that roller, and so on for as many colour rollers as are employed. To ensure that the whole surface of the fabric be brought into contact with each roller, a scraper or bar is caused to bear against the fabric where it passes around the roller, thus giving a slight friction to the cloth, and rubbing into it the colour which has been imparted to its surface. To apply damping liquid to the cloth before it passes on to the colour rollers, the inventor employs a finely perforated metal drum, mounted horizontally and with the lower part of its circumference dipping into a trough containing the liquid, whilst the cloth is led over the upper portion of its circumference. The cloth after being mordanted is made up into a roll and passed over the damping drum, which is situated between the roll and the standard carrying the colour rollers. From this it passes under and around the various colour rollers, after which it is led through nipping rollers, and is rolled off or batched at the back of the machines. The roll of cloth when taken from the machine may afterwards be steamed and heated in any way which may be requisite, according to the nature of the colouring material which has been applied.—J. H.

Improved Means for Producing Ozone and Hydrogen suitable for Bleaching Purposes. J. H. Johnson, London. From E. Hermite, Paris, France. Eng. Pat. 3956, March 20, 1886. 8d.

Improved Means for Producing Chlorine Compounds suitable for Bleaching Purposes. J. H. Johnson, London. From E. Hermite, Paris. Eng. Pat. 3957, March 20, 1886. 8d.

See XVIII., "Electro-Chemistry," p. 299.

Improvements in Dyeing Cotton, Silk, Wool, and other Textile Materials, either in the Raw State or in the Form of Yarn, or as Cloth in the Manufactured State, and in Apparatus therefor. J. Smith, Heywood. Eng. Pat. 6988, May 25, 1886. 1s. 1d.

The object of this invention is to overcome the disadvantage of having any slack or folds in the materials or fabrics, when in the tank or cistern containing the dye liquor. The material to be operated upon is first soaked in the dye liquor, and then passed by a wince on to a system of travelling lattices or rollers, in such a manner that it will accumulate and lie thereon in even continuous rows or piles. By this means a large quantity of material may be treated at once, and may also be delivered from the first set to a second, third or fourth set of travelling lattices. After being thus treated, the material is repassed over suitable rollers through the dye liquor, and again treated as above described, repeating the process as many times as may be desirable. The dyeing goes on as well during the travelling of the material as when being passed through the dye liquor.—J. H.

Improvements in Dyeing Apparatus. L. Weldon, Amsterdam, New York, U.S.A. Eng. Pat. 16,412, Dec. 14, 1886. 8d.

The inventor places the fabrics in a cylinder which revolves in a trough containing the dye liquor. This cylinder is divided into compartments with perforated sides so as to allow the passage of the dye liquor through the fabrics. The compartments are V-shaped, one side being solid and forming part of the outer edge of the cylinder.—R. L. W.

VII.—ACIDS, ALKALIS, AND SALTS.

*Pyrites.** Herbert J. Davis. Abstracted from "Mineral Resources of the United States, 1885." Division of Mining Statistics and Technology.

New Hampshire.—The ore comes from the Milan Mines, Coos County, and is of excellent quality. It is now sorted into two grades. No. 1 grade contains about 46·0 per cent. sulphur; copper, 3·7 per cent.; iron, 40·0 per cent.; silica, 6·2 per cent.; zinc, 4·00 per cent. The other grade gives about 35·0 per cent. sulphur; copper, 5·0 per cent.; iron, 30·5 per cent.; silica, 25·5 per cent.; zinc, 8·0 per cent. Smelting works for the extraction of copper and silver have also been erected, owing to the increased amounts of these metals found in some parts of the ore. The low grade sulphur ores burn very readily, and no difficulty has been experienced in finding buyers for them: the No. 1 grade, however, being in special favour.

Vermont.—No mines are at present being worked, both because the price of copper is very low, and also because the sulphur in the ores is valueless for burning purposes, the ores being, in the main, magnetic pyrites.

Massachusetts.—The only mines in this State are the Davis Mines in Franklin County. The deposit is of great extent and purity, and is of uniform quality throughout. A large reserve stock of lump, broken, and smalls is always kept on hand, usually averaging 10,000 tons. About 30,000 tons of ore were mined in 1885, its composition being—Sulphur, 49·3 per cent.; copper, 1·5 per cent.; iron, 45·3 per cent.; silica and insoluble matter, 3·8 per cent. It is intended to connect the mines to the nearest railway.

New York.—About 2,000 tons of ore were raised from the mines at Hermon, County St. Lawrence. The ore is very hard, and makes few smalls. Its analysis shows—Sulphur, 38·0 per cent.; copper, 3·0 per cent.; iron, 34·0 per cent.; silica and insoluble matter, 25·0 per cent. Another mine in Ulster County was worked for some time, until stopped by an inrush of water. The ores from this mine gave—Sulphur, 39·1 per cent.; copper, a trace.

Virginia.—In this State, the only mines are in Louisa County, and are the Arminius Copper Mines Co. and the Sulphur Mines Co. The Lennig Mines have not been worked during the year. Analysis shows the ores to contain—Sulphur, 49·5 per cent.; copper, 0·5 per cent.; iron, 43·5 per cent.; silica and insoluble matter, 6·4 per cent. New machinery for the extraction of copper, and for underground pumping, has been added. The united output of the two companies was 13,000 tons.

North Carolina.—A mine in Mecklenburgh County is being successfully worked for the extraction of gold from the pyrites, the value of the gold obtained being about 7 dollars per ton of ore. The sulphur is not utilised, the pyrites being too much mixed with rock.

Georgia.—The mines near Dallas, in Paulding County, are supplying the vitriol works at Atlanta, Georgia, and also at Nashville, Tennessee.

Tennessee.—Enormous deposits of pyrites occur, but since they are the magnetic pyrites, are of no use for acid manufacture. They have, however, been worked for copper during the last 35 years. The ores contain—Sulphur, 35·0 per cent.; copper, 5·0 per cent.; iron, 40·0 per cent.; silica, lime, alumina, 20·0 per cent.

Alabama.—The deposits have not been worked from lack of railway and other means of transportation.

Foreign Deposits.

Canada.—The output from the Albert Mine and the Oxford Copper and Sulphur Company's mines was about 35,000 tons. The mines belonging to the Canadian Sulphur and Copper Co. were idle throughout the year. The ores burn readily, and contain a workable amount of copper, and about an ounce of silver for each per cent. of copper extracted from the matte. Their average composition runs—Sulphur, 40·2 per cent.; copper (wet assay), 5·1 per cent.; dry assay, 3·8 per cent.; iron, 35·2 per cent.; silica, 19·4 per cent.

Newfoundland.—The main deposits are on the North-eastern shores, and are hence inaccessible during the greater part of the year. About 2,500 tons were raised, but did not give satisfaction.

The author then gives several tables, from which the various results for the year 1885 are extracted and subjoined:—

WORKS BURNING PYRITES, AND QUANTITY BURNED IN THE UNITED STATES.

Districts.	Number of Works.	Consumption. (Long Tons.)
Boston and Eastern District	6	25,800
New York District	7	44,600
Philadelphia District	2	11,500
Baltimore and Southern States......	3	7,500
Western District	1	2,000
Total	19	91,400

PYRITES MINED, IMPORTED, AND CONSUMED IN THE UNITED STATES.

Year.	Mined.	Imported.	Total	Consumed.	Stock on Hand Dec. 31.
	Long Tons.	Long Tons.	Long Tons.	Long Tons.	Long Tons.
1885	49,000	47,500	96,500	91,400	49,500

Of the stock in hand on December 31, there were 28,500 tons at the works, and 21,000 tons at the mines.

(*a*) Copper contents (see table at top of following page)—these are "dry assays"—1·30 per cent. less than actual (wet) assays. The Spanish ore imported has contained an average of only 1·25 per cent. copper (wet assay). Newfoundland ore contained about 3·0 per cent. (wet assay).

(*c*) All the figures for 1885 are estimated. This has been rendered necessary by the practice of some of the custom-houses not keeping pyrites separate from iron ores.

The Spanish and Portugese ores were mainly shipped as ballast in vessels carrying fruit, the rate of freight per ton to United States ports being from 2 to 3 dollars. Of these ores, about 10,000 tons contained over 3·5 per cent. copper; the remainder containing about that amount or less.

The total amount of pyrites consumed throughout the world was about 1,200,000 long tons, of which Great Britain absorbed rather more than one-half, the United States taking 91,000 tons, and France and Germany 350,000 tons.

The use of sulphuric acid is steadily on the increase in the States, a large proportion of the make, about 45 per cent., being used in the manutacture of artificial fertilisers, of which about 1,000,000 tons were prepared in this year; and there is every reason to believe that this amount will be exceeded in the future. Large quantities of the acid are also being used in the manufacture of explosives.

The imports of brimstone during the past five years average about 100,000 tons per annum, and if this amount be taken as representing the consumption in 1885, and to this be added the 91,400 tons of pyrites consumed, their sulphur contents being expressed as brimstone, the returns show an increase of 300 per cent. over those of 1878.

A considerable increase in the number of pyrites burners is also to be noted, especially amongst those already using these furnaces, the forms most in favour being the Spence mechanical furnace and the ordinary shelf burners, for burning smalls. These new furnaces are mainly congregated around New York and in New England, though several are now being built by works in the West.

Preparation of Ore.—The ore is now broken by the American producer, and sorted into the most suitable

IMPORTS OF PYRITES INTO THE UNITED STATES.

Fiscal Year Ending June 30.	CANADIAN.					Newfoundland.	Spanish and Portuguese.	Total.
	Quantity (Tons.)	Copper Contents (a).		Value.	Duty.			
		Per Cent	Pounds					
1885 (c)	34,123	3·85	2,949,363	280,189	73,734	2,500	16,600	53,223

sizes for the burners of the consumers—viz., into pieces "not larger than three inches or smaller than one inch in diameter." The smalls are screened through a quarter-inch mesh screen. Amongst the deposits in the States, it seems more than probable that the auriferous pyrites of the Rocky Mountains will be largely employed at a future date, both as a source of gold and for the supply of sulphur, inasmuch as it contains gold in quantities which, together with the burning of the sulphur, would leave a profit after paying all expenses.—S. G. R.

Improvements in the Manufacture of Sodium Carbonate by the Ammonia Process. H. Schreib. Chem. Zeit. **10**, 1585.

Nearly all the patents taken out for the production of hydrochloric acid in connection with the ammonia soda process require the ammonium or calcium chloride in a solid state. To attain this end by evaporating the liquors is out of the question, owing to its great expense. The object of this invention is the production of solid ammonium chloride in a cheap manner. The process depends on the difficult solubility of ammonium chloride in brine. If a saturated solution of ammonium chloride of 1·0765 sp. gr., which contains 288grms. NH_4Cl per litre be shaken with solid sodium chloride, the latter is dissolved and ammonium chloride is precipitated. The liquor then shows a sp. gr. of 1·1790 and contains per litre 186grms. NaCl and 177grms. NH_4Cl. If ammonia or ammonium carbonate be passed into the solution a further deposition of ammonium chloride takes place, while still more sodium chloride is taken up. This peculiarity of the ammonium chloride is made use of in the following manner. The liquor resulting from the carboniser of the ammonia soda process, and chiefly containing ammonium chloride is treated with solid sodium chloride and ammonium carbonate—*i.e.*, ammonia and carbonic acid in the apparatus shown in the diagram. The cylinder A contains the liquor, and is in connection with a smaller vessel B, which holds on a perforated bottom a supply of sodium chloride. If the valves v and v_1 are open, the liquor in A comes in contact with the salt. The large pipe in A serves for the admission of carbonic acid gas and ammonia, during which treatment the temperature in A must be kept as low as possible. The following figures show the progress of the decomposition:—

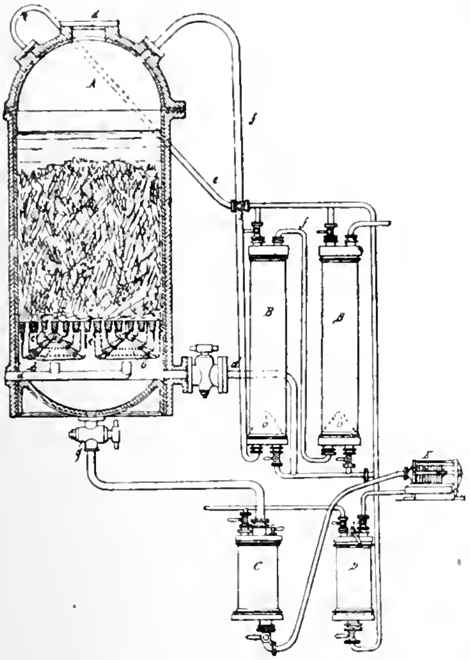
		Vol. per cent.—*i.e.*, grms. per 100cc.	
		NaCl.	NH_4Cl.
No. 1.	The liquor from the carboniser contains	9·4	19·8
No. 2.	The same liquor after the treatment with ammonium carbonate and sodium chloride cooled to 12° C.	19·3	9·0
No. 3.	The same liquor as No. 2, cooled to 10° C., and treated longer with sodium chloride	23·1	5·9
No. 4.	The same liquor as No. 3., cooled to 5° C.	25·5	4·1
No. 5.	The liquor was then separated from the solid salt and the carbonisation finished in the usual manner when the liquor tested	9·1	20·7

The liquor at the end of the operation had, therefore, practically the same composition as that used to begin with, the application of the new process not having interfered in any way with the main reaction. The ammonium chloride precipitate is washed, pressed, mixed with crushed limestone and heated for the production of ammonium carbonate, which is again passed into the cylinder A. It is claimed for this invention:

1. The ammonium or calcium chloride is obtained in a solid form.
2. The loss of sodium chloride is very small; a great deal smaller than in the usual mode of working, where the excess of salt runs away with the waste liquors.
3. The ammonia being passed into the liquor as ammonium carbonate, only one molecule of carbonic acid need be introduced into the apparatus, consequently less pumping is required. The dry distillation of ammonium chloride also requires less fuel.
4. No waste liquors.—S. H.

An Improved Method of Producing Lead Salts generally, and especially Carbonate or Oxycarbonate of Lead (White Lead). A. M. Clark, London. From O. Eyckens, Paris. Eng. Pat. 1832, Feb. 8, 1886. 8d.

This invention is based on the following reactions: A solution of lead nitrate converts metallic lead into hydrate, the oxygen required being taken from the nitrate, which is thereby reduced to nitrite. The nitrite, on a prolonged action of lead, parts with another equivalent of oxygen, forming another molecule of lead hydrate and nitrogen dioxide, which latter is reoxidised by the oxygen of the air to a mixture of nitrous and nitric acid. These two acids form lead nitrite and nitrate with the lead hydrate, and the solution of these compounds is again in a state to oxidise and dissolve metallic lead. But, apart from these neutral lead salts, polybasic lead salts are formed by the combination of lead hydrate with lead nitrite, and the patentee found that carbonic acid has the power of returning polybasic solutions of lead nitrite to a neutral condition by precipitating the excess of base in the form of lead carbonate mixed with lead hydrate, thus:—$[(NO_2)_2Pb.3PbO] + 2H_2O + 2CO_2 = Pb(NO_2)_2 + H_2O + 2PbCO_3 + Pb(OH)_2$. It will, therefore, be seen that a relatively small quantity of lead nitrite, which is constantly regenerated, converts an indefinite quantity of lead into white lead. The accompanying drawing represents an arrangement for carrying out the process in practice. The lead, after being reduced to shavings, is placed in a chamber, A, at the bottom of which is a pipe *a* for the supply of the gases required; *b* is a gas-distributor, *c* a grating for the support of the lead, *e* the inlet pipe for the liquids, and *f* an outlet pipe for the gases. As soon as A is two-thirds filled with lead and a solution of lead nitrite, a mixture of air and carbonic acid, heated to a suitable temperature is injected into the converter A, whence the gases are conducted to a series of towers, B, filled with solutions of polybasic lead nitrite, which retains all the nitrous acid which they may carry with them. The polybasic nitrite has a great affinity for nitrous acid, being thereby converted into lead nitrite. By means of a pump the liquids are frequently transferred between the converter and the towers. The white lead collects at the bottom of the converter A, where it is drawn off through *g* as fast as it is produced, in order to be filter-pressed and washed.—S. H.



Improvements in Obtaining Ammonia, Chlorine and Hydrochloric Acid from Ammonium Chloride. L. Mond, Northwich. Eng. Pat. 3238, March 8, 1886. 6d.

In previous specifications (Eng. Pat. 1886, Nos. 65, 66, 1048 and 1049; this Journal, 1887, 140. 216 and 217), the patentee described a process for obtaining ammonia, chlorine and hydrochloric acid by passing over certain oxides at an elevated temperature the vapour of ammonium chloride, and, subsequently, a current of air or steam. After the first of these two operations, some ammonia remains in the apparatus which would be destroyed by the action of air or chlorine at an elevated temperature, and it is now proposed to recover the ammonia left in the apparatus by the aid of a vacuum, or to fill up the apparatus several times with an inert gas, and exhaust it repeatedly by means of a vacuum. Instead of iron retorts which were previously recommended, the use of iron, enamelled, or lined inside with fireclay, graphite, carbon, etc., is now proposed, it having been found that the vapour of ammonium chloride gradually destroys the iron retorts. The latter may also be made of nickel or cobalt, or, better still, of cast or wrought iron, lined with nickel or cobalt, or an alloy of these metals.—S. H.

Nordhausen Oil of Vitriol Mixtures. M. Gerstner. Chem. Zeit. **11**, 3.

It frequently happens that an oleum of a certain percentage of sulphur trioxide is to be mixed with concentrated sulphuric acid in order to produce an acid with a smaller percentage of sulphur trioxide. This can be readily accomplished by the following formula:—$x = 100\frac{b-a}{a-c}$, where x represents the quantity of sulphuric acid, which must be added to 100 parts of the strong acid; a is the total sulphur trioxide in 100 parts of the acid desired; b is the total sulphur trioxide in 100 parts of the acid, which is to be diluted, and c is the total sulphur trioxide in 100 parts of the sulphuric acid to be used for diluting. The following table shows the values of a and b respectively:—

100 parts contain per cent. SO_3.		100 parts contain per cent. SO_3.		100 parts contain per cent. SO_3.		100 parts contain per cent. SO_3.	
Uncombined.	Total.	Uncombined.	Total.	Uncombined.	Total.	Uncombined.	Total.
0	81·6	15	84·1	30	87·1	45	89·9
1	81·8	16	84·5	31	87·3	46	90·1
2	82·0	17	84·7	32	87·5	47	90·3

14	8·42	29	86·9	44	89·7	59	92·5
						60	92·6

Supposing there is an acid of 25·5 per cent. SO_3 and a sulphuric acid of 98·2 per cent. SO_4H_2, and an acid of 19·0 per cent. SO_3 is required:—

Acid of 19·0% SO_3. Acid of 25·5% SO_3. Sulphuric acid of 98·2% SO_4H_2.

$$a = 85·1 \qquad b = 86·3 \qquad c = \frac{98·2 \times 80}{98} = 80·1$$

$$x = 100\frac{b-a}{a-c} = 100\frac{86·3-85·1}{85·1-80·1} = \frac{120}{5} = 24.$$

By mixing 100 parts of acid of 25·5 per cent. SO_3 with 24 parts of sulphuric acid of 98·2 per cent. SO_4H_2, an oleum is obtained containing 19 per cent. SO_3. A direct titration showed 18·5 per cent. and 18·9 per cent. SO_3.
—S. H.

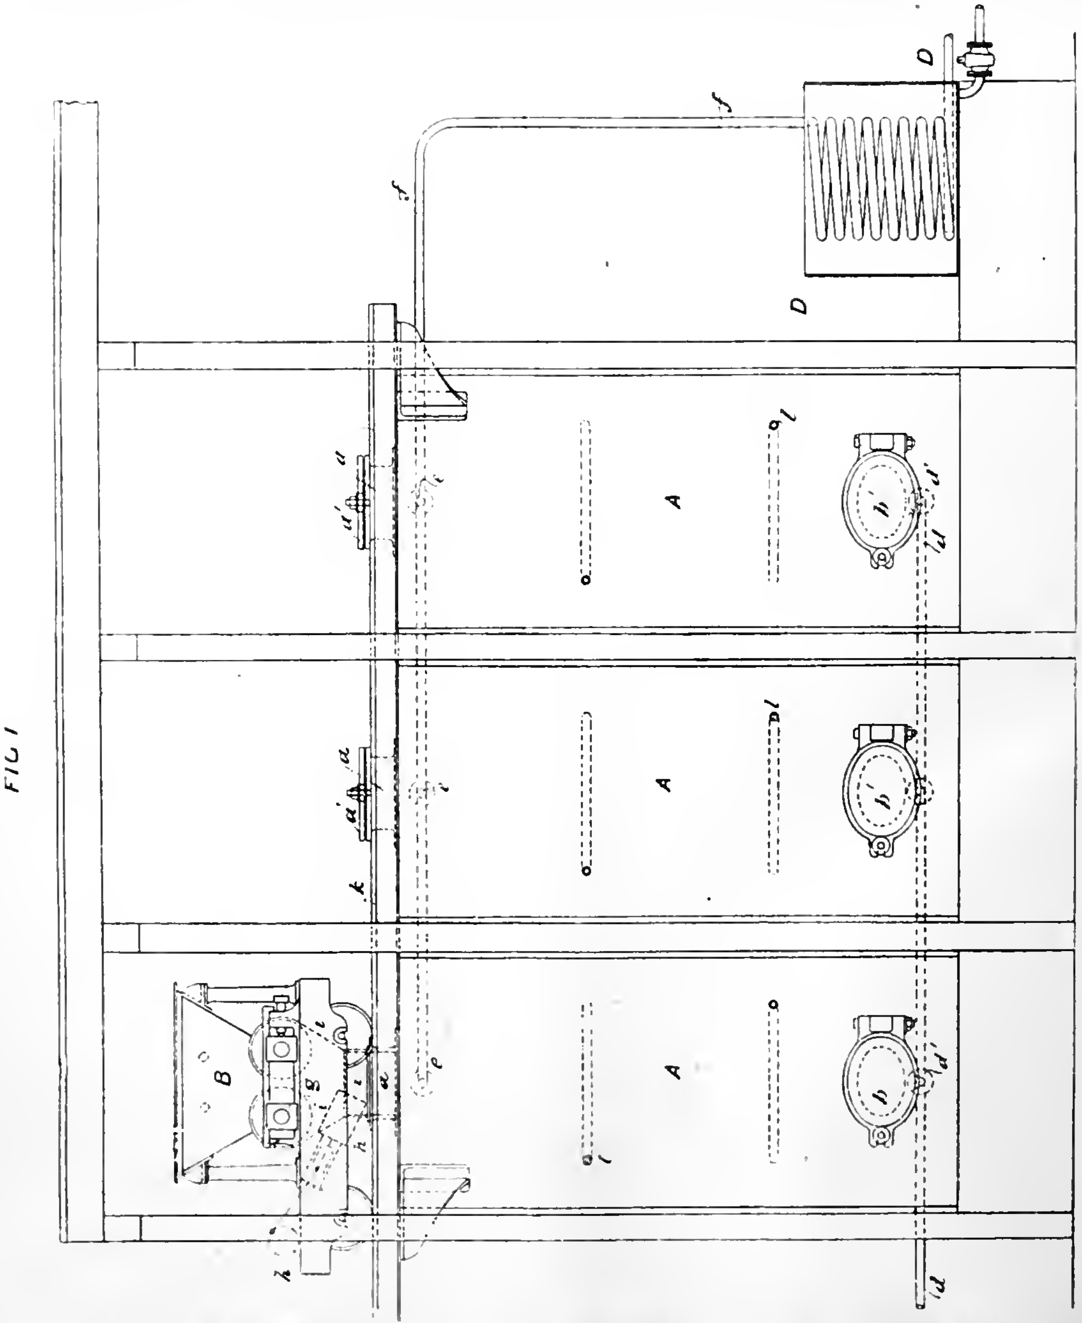
Treating Tersulphides or Polysulphides of Barium and Strontium, so as to recover the Barium and Strontium, and obtain other Products. H. L. Pattinson, Felling-on-Tyne. Eng. Pat. 4742, April 5, 1886. 6d.

In a previous specification (Eng. Pat. 16,989, 1884; this Journal, 1885, 745), the patentee described a process in which a residual liquor was obtained consisting of a solution of polysulphide of barium, or of strontium together with a little barium or strontium hydrate. It is now proposed to work up this liquor as follows :—The barium or strontium present is precipitated with sodium sulphate. The precipitate is filtered and the filtrate treated with sulphur dioxide, whereby free sulphur and a solution of sodium thiosulphate is obtained, which is evaporated and allowed to crystallise.—S. H.

A Method for Purifying Crude Carbonate of Soda, termed Black Ash, and the Recovery of Ammonia therefrom. T. Mathieson and J. Hawliczek, Liverpool. Eng. Pat. 5456, April 20, 1886. 11d.

THE black ash, manufactured by the Leblanc process, contains certain impurities, notably cyanogen and sulphur compounds, which cause much inconvenience and expense in the further treatment for the manufacture of sodium carbonate or hydrate. This invention consists in treating the black ash with superheated steam at 600° to 900° F., whereby the cyanide is decomposed, and ammonia formed therefrom, which is condensed in the usual manner. After this decomposition has taken place, the mass is treated with superheated steam of a higher temperature, when the sulphide is destroyed, giving off sulphuretted hydrogen. The formation of cyanide in the black ash is due to the presence of nitrogen in the mixing slack, and this fact is utilised in connection with the recovery of ammonia, by employing a mixing slack, containing a high percentage of nitrogen. In carrying out this invention, the black ash is broken into lumps of about three inches diameter, by the travelling crusher B (Figs. 1, 2, 3), which stands on the top of the "decomposer" A, just above the charging hole *a*. The drawings show three cylindrical decomposers A, which are provided with close-fitting charging doors *a*, and discharging doors *b*. They also contain a bed *c* (Fig. 3) for supporting the material, the bed being formed by interspaced bars. *d* are

FIG I



steam pipes, through which the steam enters the decomposers, pipes *e* being the escape pipes for the gases given off, which are conveyed to the condenser D. The travelling crusher fills the decomposers *seriatim.* When one decomposer is charged, the door *a* is closed, and steam of 600° to 900° F., passed into it. It rises through the mass, decomposing the cyanides, and escapes together with the ammonia formed through the pipes *e*. After decomposing the cyanides, steam of 1000 to 1200° F., is allowed to pass through the mass, when the sulphides are destroyed. The residue in the decomposers, now completely free from impurities, is worked up in the usual manner.—S. H.

FIG 2

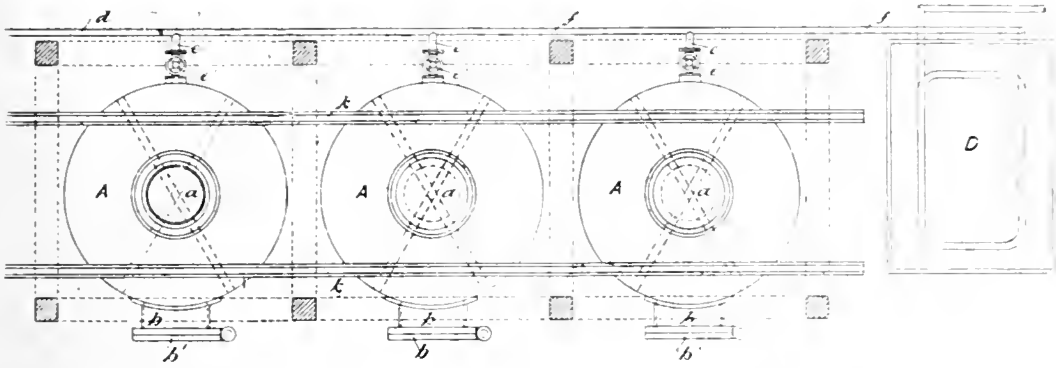


FIG. 3.

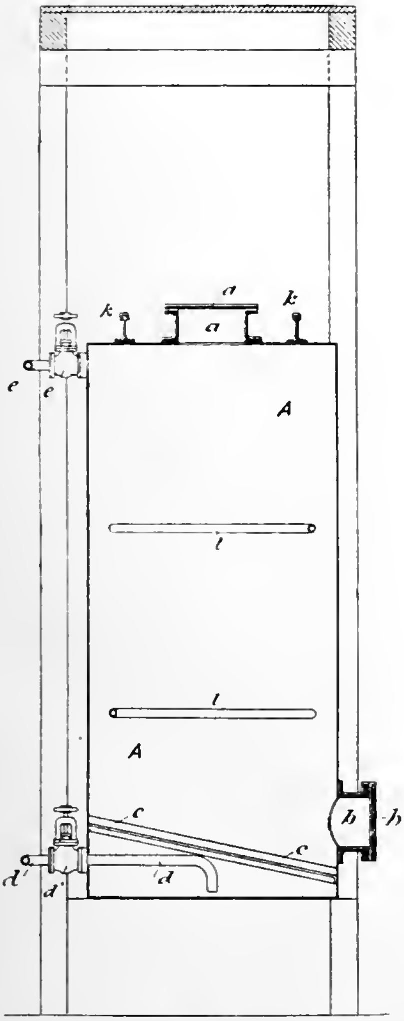


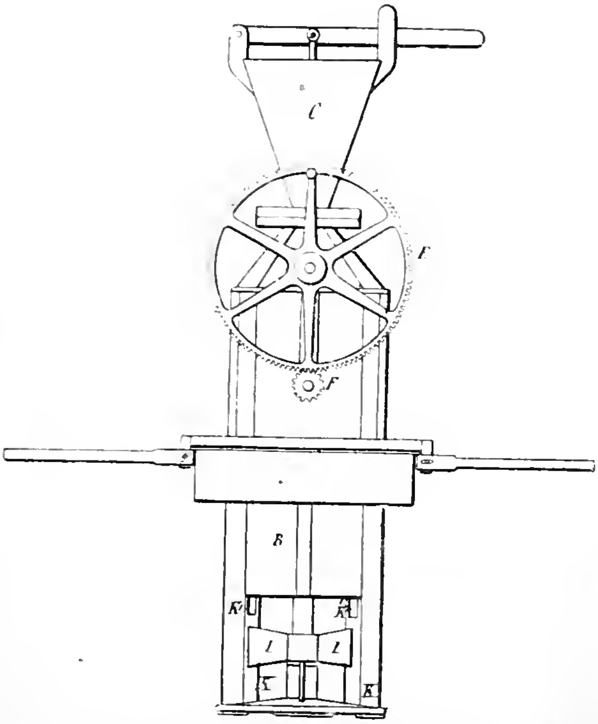
Improvements in the Manufacture of White Lead. J. Warwick, Newcastle-on-Tyne. Eng. Pat. 5820, April 29, 1886. 8d.

THE process of manufacture, as patented, consists :—1. In a method of bringing the lead to be carbonated into a state of fine division. 2. In exposing the finely-divided lead to the action of acetic acid, carbonic acid, air and moisture. 3. In an arrangement for separating the finer particles of dry white lead, in a state of very fine powder. 4. In a method whereby the separation of the remainder of the white lead is effected from any particles of lead which may have remained unconverted. In the first stage of the process, melted lead is dropped upon a rapidly-revolving disc, fixed on a vertical shaft, so that the disc revolves in a horizontal plane. The centre of the disc is slightly raised, so as to make its upper surface a very obtuse cone. The lead, thus reduced to very fine particles, is rapidly cooled. A circular chamber, fitted with a central vertical shaft, carrying upon it a series of circular horizontal shelves, serves for the conversion of blue lead into white lead. Fixed shelves are attached to the walls of the chamber, and placed between each of the revolving shelves, by which arrangement the passage of any solid material or gas through the chamber must be by a very circuitous route. On the under surface of the shelves, a series of scrapers is fixed, which cause the material on the shelves to slowly move towards the centre or circumference, in such a manner as is required to pass gradually through the chamber, from top to bottom, and over every shelf. On its way downwards, the mass meets with a current of carbonic and acetic acid, air and moisture moving in the opposite direction. The material from the carbonating chamber is emptied into a revolving drum, placed horizontally, where it is broken up by granite balls. The shaft on which the drum is hung, is hollow and perforated within the drum, so that air may be blown into the drum, whence it escapes into a large dust chamber. The air carries with it the finest particles of white lead, which collect in this chamber, as a very fine and pure preparation. With a view to preventing the loss of this light powder, the same air is made to circulate over and over again. After all this light white lead is removed, the remainder is thrown into water and ground under edge runners, to completely separate the white from the blue lead.—S. H.

Improvements in the Manufacture of Bleaching Powder and in Apparatus for Effecting the Same. J. Brock and T. Minton, Widnes. Eng. Pat. 7199, May 28, 1886. 8d.

THE object of this invention is the absorption and conversion into bleaching powder of the residual chlorine gas, which remains in the atmosphere of the bleaching powder chamber, and is not absorbed by the almost saturated lime. The inventors propose the treatment of the chlorine with lime in the form of a fine powder suspended in the atmosphere of the chamber, or in other words, the atmosphere of the chamber is to be charged with dust of lime, which readily absorbs the chlorine. If the amount of lime is in proportion with the chlorine in the atmosphere of the chamber, the resulting product is of the same strength as the bleaching powder made by the ordinary process. The apparatus for carrying out this process consists of a box or casing B (Figs. 1 and 2) which is inserted into an aperture of the chamber roof A. C is a hopper at the top of the casing, which is charged with quicklime in fine powder. D is a valve at the bottom of the hopper, and is worked by a lever arrangement in order to regulate the rate of flow. The tooth gearing E, F, G gives motion to the shaft H, which is armed with blades I, forming a fan, or distributor. Bearings for the shaft are provided upon the casing. The lower bearing is supported by the tubes K, which are ranged around the fan. The tubes are open at the bottom, and there are apertures in them at K', directed inwards, so that an upward current is maintained through the tubes and out through the apertures K' whenever the fan is in motion. This current meets the lime descending from the hopper, passes with it to the fan, and then issues all around between the tubes K, thus causing the finely divided lime to pervade every part of the chamber. Three of these machines will be found sufficient for a chamber of 100ft. length.—S. H.

Fig 1



Improved Process, or Means for Expelling Sulphuric Acid in Excess from Sulphates and Bisulphates. J. H. Johnson, London. From J. L. Kessler, Clermont, France. Eng. Pat. 5016, April 10, 1886. 6d.

It is proposed to roast the bisulphate with certain reducing agents at a low red heat, only the "free sulphuric acid" being thus decomposed. A neutral sulphate remains.—S. H.

An Improved Process for Obtaining Crystallised Sulphate of Calcium. E. A. and E. M. Arthur, Tiverton-on-Avon. Eng. Pat. 4070, March 23, 1886. 4d.

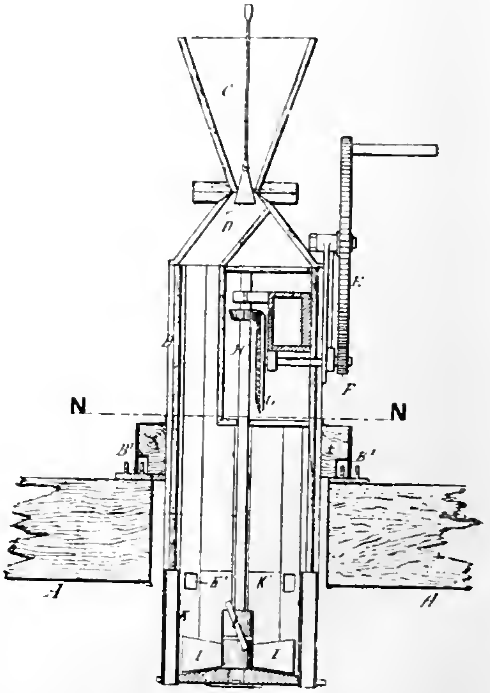
A SOLUTION of calcium chloride, "resulting from any process of manufacture of soda involving the use of ammonia," is converted into calcium sulphate, which is known commercially as pearl-hardening.—S. H.

IX.—BUILDING MATERIALS, CLAYS, MORTARS AND CEMENTS.

Delune's Drain Pipes, made of Cement Concrete. Rev. Indust. 1886, 76.

The pipes consist of two parts, each part being composed of different materials. The lower is made of hard watertight concrete, with a perfectly smooth inner surface. It serves as the gutter. The upper portion consists of very permeable concrete, consisting of 8—10 parts broken stones and 1 part cement, which latter must be of a very perfect description.—A. R.

Fig. 2



Improvements in the Manufacture of Fire Bricks, Retorts, Crucibles, and other Fire-Ware Goods. S. J. Payne, West Thurrock. Eng. Pat. 3391, March 10, 1886. 4d.

The goods are manufactured from a mixture of either clay, ganister, graphite, millstone grit, flint, sandstone, sand, loam, spent lime from gasworks, etc. (burnt or unburnt), or of several of these materials with Portland cement and "slurry." The mixture, brought to a proper consistency, is moulded by hand or machinery, and kilned.—E. G. C.

Improvements in Compounds for Coating and Finishing Walls and the like. E. A. Bronson, Nebraska, U.S.A. Eng. Pat. 16,926, Dec. 24, 1886. 4d.

The object of this invention is to provide a composition for coating and finishing walls, which shall be entirely free from lime, and will not shrink, crack nor expand. The constituents of the compound are plaster-of-Paris, sand, Keene's cement, glue and marble dust; a suitable colouring matter being added if desired. In applying the compound to the wall or ceiling, a groundwork or base of plaster-of-Paris, sand, whiting and glue is first applied and allowed to set. By the use of this composition, it is stated that a wall or ceiling is rendered rat and vermin proof, as well as impervious to moisture and frost. —E. G. C.

Improvements in the Manufacture of London Artificial Asphalt. W. E. Constable. Eng. Pat. 3832, March 18, 1886. 4d.

Hard limestone, preferably Derbyshire limestone, is crushed by edge runners or other suitable machinery, and heated to 120—130° F. in order to remove moisture. It is then mixed with refined distilled tar (freed from oil, creosote and water), and the material thus prepared should be stored for about three months. The approximate proportions are—1 ton crushed limestone and 12 gallons distilled tar. For the preparation of artificial asphalt, the base material so prepared is mixed with bitumen, lime and sulphuric acid.—E. G. C.

An Improved Mode of, and Apparatus for, Continuously Manufacturing Portland Cement. W. Sonnet, Boeckum, Germany. Eng. Pat. 17,098, Dec. 30, 1886. 8d.

The raw materials, properly mixed and finely ground, are sifted upon a sieve of 900 meshes to the square centimetre, and carried at once, by means of a conveying worm, into a serpentine channel-shaped furnace of peculiar construction, and there burnt. The "burning" furnace is heated to from 2500° to 3000° C., and the raw material, during its passage through the conveying worm, is heated to from 100° to 150°. By the use of this invention the burning of the cement proceeds continuously, moistening, forming into slabs, drying the slabs, the setting-in of the same, and the drawing-out of the cement-mass while hot from the furnace (as in the old process), are all dispensed with. The entire mass to be burnt is conveyed automatically to the furnace, and 75 per cent. of the burnt mass is carried out automatically, leaving only 25 per cent. to be removed from the furnace, "and that easily by hand labour from outside." The cement produced, will be free from remaining portions of fuel and raw cement material. Also, the cost of manufacture is considerably diminished, while the workmen are much less exposed to dust and heat than in the processes heretofore employed. The construction of the serpentine "channel-furnace" is detailed in the specification.—E. G. C.

X.—METALLURGY, Etc.

The Influence of Silicon on the Properties of Iron and Steel. Part I. Thomas Turner. Jour. Chem. Soc. **1887**, 129.

This paper is really a continuation of the author's previous work on cast-iron (*Jour. Chem. Soc.* 1884, p. 260; 1885, pp. 474, 577, 902; 1886, pp. 130, 215, 493; *Jour. Iron and Steel Inst.* 1886, Part I.; this Journal, 1886, p. 289), though the present contribution marks a new departure, and has to do with wrought-iron and steel as distinct from cast-iron. A brief outline of the work of other observers is given, and it is concluded that the present state of our knowledge on this subject is probably as follows:—

1. *In Ingot Iron.*—Silicon promotes soundness; it resembles carbon in increasing the tenacity and hardness; it should not exceed 0·15 per cent. in metal which has to be rolled; in some cases it produces brittleness when cold.

2. *In Steel Castings.*—Silicon promotes soundness: it is, however, regarded as a necessary evil, and excess should be avoided, as tending to brittleness and low extension; about 0·3 per cent. is generally recommended.

3. *In Crucible Steel.*—A few hundredths per cent. is necessary to produce soundness; it is generally agreed that considerable quantities of silicon may be present without injury.

4. Manganese appears to be capable of neutralising the ill effects due to silicon. The effect of carbon in presence of silicon is doubtful, but is probably detrimental.

The author has examined the effect of silicon on the purest iron obtainable in commerce. For this purpose metal was taken from the Bessemer vessel, at the end of the blow, just before any addition of ferromanganese was made. This contained 0·0098 per cent. of silicon, and was mixed with different proportions of silicon pig-iron, containing 10·3 per cent. Si. The mixture remained quiet in the mould when only a few hundredths per cent. of silicon were added. The metal was originally red short, especially at a dull red heat, though it worked well at a welding temperature: the red shortness was increased by silicon. The metal was tough cold, and welded well, silicon having little or no influence. Silicon increased the elastic limit and tensile strength, but diminished the elongation and contraction of area, a few hundredths per cent. having a remarkable influence in this respect. The appearance on fracture changed from finely silky to crystalline, while the hardness increased with the increase of silicon, but appeared to be closely connected with the tenacity. With 0·4 per cent. of silicon a steel was obtained, difficult to work when hot, but tough when cold, capable of being hardened in water, and giving a cutting edge which resisted hard usage.

The author is indebted for assistance in his work to Professor Kennedy, Mr. Harbord, and Mr. Walton.

On the Manufacture of Crucible Steel. F. C. G. Müller. Stahl u. Eisen, **1886**, 704.

It is generally admitted that the best steel for making tools should not contain any impurities besides carbon; mere traces of phosphorus, sulphur and copper being especially objectionable. These are not especially affected by the crucible process; but, on the other hand, silicon is here of fundamental importance, as it is always taken up by the steel, except when basic crucibles are used. The fear with which some metallurgists regard this element is excessive, considering that the best English cast-iron may contain as much as 0·5 per cent. of it. It has been proved, in the Bessemer and Martin processes, that the addition of a small quantity of silicon prevents the liberation of the hydrogen, which is always present in iron. The reduction of the silica may be effected by carbon or by manganese, according to local circumstances. Manganese should not be used when raw steel containing very little of it has to be fused in crucibles rich in carbon. On the other hand, it is advantageous to use manganese, when steel for tools has to be made from raw Swedish iron, since it refines the iron without loss of carbon or of gas, and eliminates an excess of manganese from the steel. The part played by the manganese is all the more important when there is but little carbon in the clay used in making the crucibles, for this often does not contain sufficient to reduce enough silica: hence the necessity of adding some manganese. The steel for tool-making manufactured in some of the most renowned English works contains as much as 0·25 to 0·35 per cent. manganese, and this can only have been added in the form of alloys or readily reducible compounds of manganese, when working with rich Swedish pig-iron. —E. E. B.

Improvements in the Manufacture of Castings from Wrought-iron and Steel. T. Nordenfelt, London. In part from C. G. Wittenström, Stockholm, Sweden. Eng. Pat. 8269*, July 8, 1885. 4d. Amended Specification.

The emendation consists in the deletion of the clause stating that the aluminium may be added at a period earlier than "when molten and shortly before it is to be poured."—W. G. M.

Improvements relating to the Uniting of Platinum or Silver and Nickel, or Alloys of these Metals. H. H. Lake, London. From La Société de Laminage du Nickel, Paris, France. Eng. Pat. 1473, Feb. 1, 1886. 6d.

To produce compound plates or wires of platinum or silver, or their alloys, with nickel or its alloys, the two surfaces to be united are exactly fitted to ensure perfect contact throughout; they are then sprinkled with a flux (one surface may be electro-plated with a metal which will act subsequently as a solder), heated to a sufficient temperature, and welded by hammering or rolling. To prevent oxidation of the nickel during the heating process, the plates are wrapped air-tight in thin sheet-iron envelopes lined with an earthy substance to prevent adhesion of the contained metals, these cases being removed finally by scaling or scouring.—W. G. M.

Improvements in the Method of and Means for Extracting the Tin from Tinned Sheet Metal Cuttings by Means of Hydrochloric Acid Gas. F. Bosshardt, Manchester. From S. Montagne, Nantes, France. Eng. Pat. 2865, Feb. 27, 1886. 8d.

THE cuttings are heated to 150–160° C. by steam in a closed vessel, into which hydrochloric acid gas is led from an adjacent generator; by this means the tin is completely converted into stannous chloride, the latter being washed away by water pumped into the vessel from above, and distributed through a rose jet. The solution of chloride is treated with zinc, or in any convenient manner for separating the tin. The scrap iron, denuded completely of tin, may be worked up into bars.
—W. G. M.

Improvements in the Manufacture of Open Hearth Steel. W. Penrose and W. Hackney, Swansea. Eng. Pat. 4536, April 1, 1886. 8d.

THE object of this patent is to lessen the time required to work an open-hearth charge, by facilitating the oxidation of the metalloids. This is effected by granulating the pig-iron, mixing with it a suitable proportion of an oxide ore, and introducing the charge, with or without admixture of lime, through apertures in the furnace roof. The quantity of oxide must be so calculated that the decarbonisation shall be complete at the moment when the metal is melted and at the requisite temperature for tapping.—W. G. M.

A New Manufacture of Fibrous Iron. A. de Laude Long, Stockton-on-Tees, and R. Howson, Middlesbrough. Eng. Pat. 5527, April 21, 1886. 6d.

MILD steel with any suitable percentage of carbon is granulated, then balled up in a furnace with a cinder bottom, squeezed and subsequently treated as puddled iron. During the working of the slag hearth, a portion of the slag becomes worked into the metal, and thus a fibrous iron or steel may be prepared from a mild steel.
—W. G. M.

XI.—FATS, OILS, AND SOAP MANUFACTURE.

Improvements in the Preparation of Emulsions of Vegetable, Animal, and Mineral Oils, of Solid Paraffins, Waxes, and Fatty Substances, and of Liquids which are insoluble or but partially or slightly soluble in Water. A. Blackie, Wadhurst. Eng. Pat. 3266, March 11, 1886. 6d.

FOR vegetable or animal oils, and for chloroform and similar liquids slightly soluble in water, the patentee prepares a solution of gelatin or size, containing 4oz. dry material to the gallon, and in 12 parts by weight of this, 1 part of an alkaline carbonate or phosphate is dissolved. With this, when cool enough, from 24 to 36 parts of the oil or other liquid are incorporated. For mineral oils—benzoline, naphtha, etc., 1lb of soft soap is dissolved in a gallon of water, and 6oz. of size are added. The use of alkaline sulphides, or of arsenic dissolved in glycerin, in connection with these emulsions when used for destroying parasites, is also claimed.
—W. L. C.

An Improved Lubricating Composition. B. J. Hicks and J. Kirkwood, Middlesbrough. Eng. Pat. 3518, March 12, 1886. 6d.

IN order to absorb the heat of friction in the bearings of heavy machinery, whereby the lubricant is often reduced to a thin wash, the patentees mix a large quantity of decaying vegetable matter, such as cabbage or potatoes, with the ordinary lubricants employed for such purposes, such as animal fat, pitch, etc., with or without plumbago and whitening.—W. L. C.

Improved Means Applicable for Use in Extracting Oils by Volatile Solvents. A. W. MacIlwaine. Eng. Pat. 3644, March 15, 1886. 4d.

To avoid the deterioration in colour produced in some oils, especially rape-seed, by the use of iron vessels and pipes for this operation, the patentee claims the use of vessels made of or lined with lead or other suitable metal or alloy.—W. L. C.

Improvements in Apparatus for Separating Mineral or other Oils from Oils or Substances of different Specific Gravities. A. F. Craig, Paisley, A. Nelson, and J. Snodgrass, Inkermann, N.B. Eng. Pat. 3749, March 17, 1886. 8d.

THIS apparatus is of the centrifugal class, and comprises a rotating vessel having impermeable sides, which may be placed with its axis in any position, though the vertical is preferable. The oleaginous mixture to be operated upon, may be supplied so as, when thrown by the centrifugal action against the sides of the vessel, to proceed either upwards or downwards. An annular channel is arranged by the flaring of the sides of the rotating vessel at the larger end with one or more outlet passages. Further description would be unintelligible without the drawing given.—W. L. C.

An Improved Lubricating Compound. T. L. Wade, Glasgow. Eng. Pat. 4404, March 29, 1886. 4d.

CASTOR OIL, sperm oil and mineral oil, are mixed in varying proportions, and heated by steam in an air-tight tank provided with a low level air inlet and an air outlet. Air is exhausted from the surface of the oil, and this causes a violent current of air to pass through the hot oil, thus removing all traces of moisture.—W. L. C.

XII.—PAINTS, VARNISHES, AND RESINS.

New Caustic Powders for the Removal of Paint and other Deposits, applicable also for Cleansing and Disinfecting Purposes. Baron de Liebhaber, London. Eng. Pat. 4737, April 5, 1886. 6d.

THESE powders, designated under the generic name of "Tologen" consist essentially of lime and alkaline compounds. (1) Caustic Tologen: Ground quicklime in sufficient quantity is evenly distributed in a strong sodium hydrate solution, and the mass heated. On cooling it becomes solid and pulverulent. (2) Sodic Tologen: It consists of a mixture of sodium carbonate and quicklime in suitable proportions. (3) Oxalic Tologen: It is prepared by mixing potassium bioxalate with quicklime, to which some sodium carbonate may be added, if its action is desired to be less energetic. (4) Chlorinated Tologen: It is obtained by mixing quicklime with a solution of sodium or potassium hypochlorite. (5) Prussic Tologen: It is a mixture of quicklime with potassium cyanide solution.—S. H.

XIII.—TANNING, LEATHER, GLUE, AND SIZE.

Improvements in the Manufacture of Tannin and Similar Vegetable Extracts, and in Apparatus Employed therein. A. Morand, Philadelphia, U.S.A. Eng. Pat. 4392, March 29, 1886. 8d.
